BRAIN ABSCESS AS THE OTOLOGIST'S PROBLEM*

O JASON DIXON, MD
KANSAS CITY, MO

The greatest problem in the successful management of a brain abscess is in the diagnosis of the lesion. If the medical profession is to make any satisfactory progress in the management of the disease, the physician must first determine why a patient suffering from a brain abscess so frequently goes unrecognized until it is too late for surgical intervention.

Bagley¹ has aptly said that the fear of the presence of a brain abscess frequently prevents the physician from facing the unpleasant situation until the appearance of grave symptoms. In one way, a brain abscess offers the physician more than any other pathologic lesion because he knows that it is always fatal if not operated on. There is no organ in the human body that can conceal its trouble so carefully as a brain which harbors an abscess. Nor is there a pathologic lesion that explodes with such sudden and fatal results.

Eagleton² has compared a patient with a brain abscess to a hibernating animal, in that the patient has a subnormal temperature, tachycardia, slowed respiration with diminished output of carbon dioxide, lowered blood pressure, relative peristaltic inactivity, and a reduced insensibility to painful and emotional stimulus. It is no wonder that the otologist so frequently fails in the early recognition of the vague, yet important, symptoms. He diagnoses disturbances elsewhere in the body by deformity, inflammation, pain, fever and impairment of function. All of these may be so slightly disturbed by a brain abscess as to pass unrecognized. I believe he has been led to overrate the value of neurologic observations in the early diagnosis of brain abscess and has neglected the most important aid—the history.

Neurologic anatomy is so complicated that, by his absence of knowledge of the subject, the otologist excuses his own lack of skill in the recognition and diagnosis of neuropathologic lesions. This defense is unfair when one considers the large proportion of brain abscesses that do not show particularly in their early course, any positive neurologic signs.

Lund³ states that "the chief reason of the high mortality rate is that, of all the otogenic complications

the brain abscess most frequently escapes being recognized in due time."

Korner⁴ first established the fact by a large series of necropsies that in more than 85 per cent the brain abscess was adjacent to the original focus of infection. Von Bergmann,⁵ as early as 1888, determined that a primary focus was always necessary in the formation of a brain abscess. Available statistics show that over 50 per cent of all brain abscesses are otogenous, and, of this number, about 80 per cent arise as a complication of chronic mastoid disease. Lund³ has shown in a series of fifty-four cases, which were completely studied, that more than half of them were secondary to cholesteatoma.

From the foregoing remarks it is quite obvious that brain abscess is, in the beginning at least, an important otologic problem and ranks along with meningitis and sinus thrombophlebitis as one of the three major complications of otitic disease. Since any of these diseases may exist as a complication of the other, it seems to me that the management of brain abscess is just as much the responsibility of the aural surgeon as is the sigmoid thrombophlebitis or the otitic meningitis. Also the brain abscess, which is most amenable to treatment, is the one that lies in close proximity to the affected mastoid. Certainly the approach to the otogenic brain abscess falls within the field of the otologist, and the drainage of the abscess is usually a minor part of the operation.

Dandy⁶ has brought out the importance of the value of a minimum of surgery and slow drainage of the abscess. A rubber catheter is used, which is removed in from forty-eight to sixty hours. There is no irritation and no finger exploration. The brain tissue is not removed, and there is only a nick in the dura to permit the entrance of the drain.

PATHOGENESIS OF BRAIN ABSCESS

The exact development of this lesion is not accurately known. Experimentally, it is very difficult to produce. The clinical observations, which are confirmed by operation and by necropsy studies, have not afforded a large enough series to determine all the different stages in the development of this disease. It is known, however, that the time of development may vary from a few days to several weeks and that a patient may harbor a brain abscess for as long as sixty-four years. The average duration is four and one-half weeks and should be considered the maximum time limit for handling this disease.

The stages of development may be divided into four parts—the initial, latent, manifest and terminal. These

may all vary and they frequently overlap. The patient is usually diagnosed in the manifest or terminal stage, at which time he has two classes of symptoms: general or systemic, and local or brain symptoms. Under general is a marked lethargy, sallow complexion, slow respiration, loss of appetite, constipation and subnormal fluctuations of temperature of about 2 degrees. The most characteristic finding in the history of a patient with a brain abscess is the negative stage; he has no complaints except one—headache—which falls under general brain symptoms, and unless he is in a late or terminal stage, headache is the most constant and important symptom. The headache that a patient with a brain abscess complains of is unlike any other type of headache, except possibly that of brain tumor. It is unrelieved by any form of medication; it is constant,

Cytologic examination of the spinal fluid gives various results with the different stages of the abscess. The chief diagnostic aid in the study of the spinal fluid is whether the patient has a sterile or a septic meningitis. The pressure readings of the spinal fluid, and the reaction of the patient following these lumbar taps is, in some cases, of striking importance. It should be borne in mind that, in every patient with a brain abscess, the primary stage is closely associated with a diffuse meningitis, particularly in abscesses of otogenous origin and may at the onset present such a confusing picture as to make a differential diagnosis impossible (case 3).

ILLUSTRATIVE CLINICAL CASES

CASE 1—One interesting case of a brain abscess has recently come under my observation which not only explains one of the ways in which an abscess may form but also its duration. A man, aged 30, was admitted to the hospital with his first attack of mastoiditis. During the mastoidectomy the surgeon curetted some tissue which he thought was thick pus. This was sent to the laboratory, and the pathologist pronounced it brain tissue. The patient developed severe headaches, with a rise in temperature to 103 F. Five weeks later the necropsy revealed a fully developed brain abscess at the site of curettement. The abscess had ruptured, producing a diffuse meningitis. This is the only case of brain abscess coming under my observation in which the exact time of the onset could be precisely determined.

CASE 2—Miss M. T., aged 21, was admitted to the Isolation Hospital, March 3, 1924, with measles. Four days later she developed a supra-orbital swelling. There was a profuse straw

Fig 1 (case 4)—Pulse and temperature showing rise following rupture of the brain abscess

it gets progressively worse, and, were it not for the lethargic state into which the patient rapidly sinks, it would no doubt be the means of rescuing him from his disastrous condition more frequently than any other symptom. Other general brain symptoms which are usually present are vertigo, sudden vomiting, slow cerebration, bradycardia, photophobia and, last and of most infrequent occurrence, optic neuritis.

Since this paper does not deal with the localization of the brain abscess, that part will not be considered. However, cranial nerve lesions do play an important diagnostic part, and particularly is this true in lesions of the third, sixth and seventh cranial nerves of uncertain etiology.

SEROLOGY

The patient with a brain abscess usually has about 12,000 leukocytes and a moderate decrease in the red blood cells and hemoglobin, as the disease progresses

TABLE 1—Location of Abscess

colored, watery discharge from both nares and she complained of a slight frontal headache. The following day this condition resembled erysipelas, but her general condition improved; her temperature subsided and she had less headache. Five days later the swelling became localized and when incised over the inner canthus an ounce of thick yellow pus was drained off. The wound healed promptly.

Without warning, her left ear discharged at this time. She had no symptoms of mastoiditis. Apparently this was a very mild type of ear infection as the discharge rapidly diminished and the patient made no complaint relative to the ear. In fact, she made no complaint about any of her illness, insisting that she had no headache and no pain. She was quite listless but answered questions in a normal manner and seemed to resent any examination or disturbance. Her general condition seemed to be improving. Her temperature was never above normal, she lost no weight, ate well and slept well. However, she did have some unusual symptoms. She frequently had urinary incontinence and at one time the nurse noticed that she removed the packing from her supra-orbital wound and reinserted it with her nail file. She swore at the nurses and was quite vulgar in her conversation. I reprimanded her severely about this, but she was not disturbed and apparently took no offense.

April 1, nearly a month after her admission, in making the rounds I noticed that she was standing at a window on the second floor laughing and joking with friends on the outside of the hospital. She apparently was in good condition and I did not examine her.

The following day she became quite listless and paid no attention to her surroundings. This condition gradually became worse, she seemed to fall into a natural sleep and had a shuffling,

slow respiration and a regular full pulse of 50. She refused food and water.

I suddenly realized that I was dealing with an intracranial disturbance, but owing to the fact that she had a septic focus in her left ear and also one in her left frontal sinus, and with no localizing signs, it was difficult to determine which area of her brain to explore. Neurologic consultation was no help. Remembering that the left frontal sinus was involved first, I decided to expose the left frontal lobe.

The frontal sinus showed evidence of long standing infection and an abscess containing about 2 ounces (60 cc) of thick white pus, under considerable pressure, was opened in the left frontal lobe of the brain. Immediately the respiration and pulse became faster and stronger and the following morning she ate a hearty breakfast and carried on a particularly jovial conversation. She remembered little of her stay in the hospital and nothing at all of the preceding five days.

She had a paralysis of her sixth cranial nerve which promptly cleared up and she made an uneventful recovery. There was a moderate bilateral choked disk which was discovered only the day prior to operation.

It is difficult to understand how a patient with such extensive brain involvement could have passed unrecognized while constantly under one's observation. Three weeks elapsed from her first definite symptoms of brain abscess until she was operated on. This period corresponds exactly with that experienced by Bagley,¹ who was also at a loss to explain such dangerous delays. I repeatedly insisted on a more complete history in this case, but the interns were unable to obtain it because the patient had no relatives in the city.

Patients do not suddenly develop urinary incontinence without cause, and the peculiar mental state which aroused my early attention should have brought forth a closer study of this patient. Her serious and almost fatal preoperative condition shows how hazardous it is to wait for definite localizing signs prior to operation. Such a procedure usually offers the pathologist an opportunity to make the intracranial observations at autopsy.

CASE 3—Sept 27, 1927, J. G., a painter, aged 29, was admitted to the Isolation Hospital with a diagnosis of otitic meningitis. He had a draining right ear which had been present for twenty years, since an attack of measles, but this ear had caused him no particular trouble until the night of September 22, when it felt full. He went to a doctor and had it washed out. Four days later he was unable to reach the doctor's office on account of a chill followed by high fever, a severe bursting headache, projectile vomiting, delirium and weakness.

On admission, his temperature was 104.6 F. The white blood cell count was 12,600, 85 per cent hemoglobin, a normal urine and 15,500 cells in his spinal fluid, which were mostly polymorphonuclear. A smear of this spinal fluid showed, when stained, a mixed flora of bacteria with staphylococci and streptococci predominating. There was slight tenderness over the mastoid process but no swelling or redness. From the canal a small amount of foul smelling pus was exuding. The ear drum was gone. I concurred in my interns' diagnosis of otitic meningitis and advised the patient's relatives that nothing could be done for such a condition and that he would die.

Immediately following the spinal puncture the patient began to improve. His headache disappeared, he talked rationally and he ate his food without help, but he had no appetite and appeared very dull mentally. His fever subsided, and four days later another spinal puncture yielded much to our surprise, only 150 cells with marked decrease in pressure and no organisms. After twenty-four hours there was no growth of bacteria from the cultures, and I suddenly awakened to the fact that I was dealing with a brain abscess of otitic origin.

The following morning a radical mastoidectomy was performed on the right ear, the dura of the middle fossa was covered with old dense granulations, through which yellow globules of pus were oozing. When the dura was incised, about

2 ounces (60 cc) of yellow, foul smelling pus oozed forth. The patient rapidly improved while on the operating table. A catheter was inserted as a drain, and that afternoon the patient smoked a cigaret and wanted to know how the world series baseball games had come out. The patient made a complete recovery and has been well since.

It was rather by accident that this patient was operated on for brain abscess. Had not the second lumbar puncture been done and the patient showed such striking symptoms of brain abscess, I would have accepted the otitic meningitis as a hopeless condition.

I recall, with regret, similar patients who have come under my observation and on whom I was satisfied to accept the diagnosis of otitic meningitis as a fatal terminal event. Perhaps none of them might have made the spectacular response to surgical intervention that this patient did, but they were entitled to more careful and optimistic consideration. The only way that I can understand this patient's recovery, after streptococci were demonstrated in the spinal fluid is that he

Fig. 2 (case 4)—Appearance of brain after fixation showing the bilateral abscesses.

developed a systemic immunity to the infection as well as a local walling off of the abscess.

This unusual spinal fluid finding with recovery is similar to case 4, except that the latter patient, after having recovered from his meningitis, developed multiple brain abscesses which were not drained.

CASE 4—Jan 25 1925, a man, aged 40 was brought to St. Luke's Hospital with the following history:

Nov. 2, 1924, while working as a carpenter, a scaffold collapsed and the patient fell about 12 feet. He landed in the debris on his buttocks and was momentarily unconscious. He felt no discomfort at the time, and helped remove his partner, who appeared to be more seriously injured.

On the advice of his foreman he went home, and that night his wife noticed that he bled from his left ear. The following day he had quite a profuse epistaxis, which was uncommon for him. He felt well enough to work the following day but was advised by his family not to do so. Two days later he drove his car 70 miles and for the first time complained of a severe frontal headache. Two days after that he took quite an extensive motor trip to a neighboring state and was gone six days.

On his return his relatives noticed that he was much slower in his movements and did not answer questions promptly. He tried to chop wood but was too weak.

His condition remained about the same for a month, when he developed a right earache. The drum was incised, producing a purulent discharge and relief of pain. One week after this he became semiconscious and had several severe vomiting attacks. This was followed two days later (December 17) by convulsions, with head and eyes turned to the left, and his head drawn back. His temperature varied at this time between 102 and 106 F. During the first twenty hours he had fifty-two convulsions. A lumbar puncture revealed a cloudy spinal fluid with normal pressure and no demonstrable organisms either by smear or by culture. A cell count was not made.

His family physician quite naturally diagnosed a nonepidemic meningitis, but much to the physician's surprise, within three days he seemed to improve. The convulsions stopped, and although he was semidelirious and had intermittent attacks of projectile vomiting, the elevation of temperature subsided and he began to eat and regain some of his strength. His pulse rate did not go above 48.

At this time (Jan 25, 1925) he was brought to the hospital. He was in a fair state of nutrition and appeared uninterested in his surroundings. He did not look very sick. His response to questions was slow and it was difficult to get his cooperation in the examination. He apparently had some impairment in his hearing. In his right ear was a dried purulent discharge, and the left drum was normal. There was no evidence of injury about his head. The pupils were round, regular and equal, and reacted normally. There was a moderate increase in the swelling of the optic nerve heads, more marked on the left side. The tongue was moist and protruded normally. The pulse rate was 46 and regular, hemoglobin was 85 per cent, white blood cells, 12,400, red blood cells, 4,700,000.

The blood Wassermann reaction was negative.

February 3, after observing him for one week without noting any change in his symptoms, I decided to go in through the frontal sinus and explore the silent area of the brain, selecting this site partly on account of the suggestive roentgenographic observations, but principally because an abscess in this portion of the brain could explain the negative localizing signs.

After opening into a normal frontal sinus without evidence of fracture, I removed the inner table and uncovered an arachnoid, which expanded with each inspiration. The dura was incised and a large lumbar puncture needle was inserted. A small amount of caseous material was removed, but no frank pus. A soft rubber drain was inserted $1\frac{1}{2}$ inches. There was practically no drainage through the tube. It was removed on the fifth day. The wound healed without infection.

One week later the brain was again explored for an abscess. The frontal wound was reopened. A trephine opening was made over the right temporofrontal region and the right mastoid opened, exposing the dura of the middle fossa. From these openings the brain was explored thoroughly in every direction, both with a needle and with a thin narrow spatula. No pus was found and the patient was returned to his room. He made no improvement and died ten days later (fig 1).

Necropsy revealed multiple abscesses involving both anterior hemispheres of the brain (figs 2 and 3). The right abscess had

ruptured into the right ventricle, producing a diffuse meningitis. There was no evidence of any primary focus or skull fracture. The mastoid was normal.

It is pathetic to fail in localizing a brain abscess when one feels so certain that an abscess is present. The autopsy observations made the effort seem all the more futile.

This case brings out two interesting points: first, the enormous amount of brain involvement with a total absence of localizing symptoms; second, the difficulty of locating a brain abscess at operation.

CASE 5—Jan 13, 1930, a boy, aged 8 years, was admitted to my service for a mastoidectomy. Following an attack of measles at the age of $2\frac{1}{2}$ years, he had had severe pain in his right ear. The ear did not drain and caused him no further trouble until Dec 7, 1929. Following a severe head cold at this time he had severe pain for about ten days and a temperature of 104 F; he was delirious and had urinary incontinence and disorientation. He was dizzy and was unable to walk alone, he complained bitterly of frontal headache, talked incoherently, and was unable to recognize his mother. At times he was unconscious, and he complained of being short of breath. He said that his head felt big.

December 24 I incised the ear drum. There was a profuse discharge of pus under pressure and he promptly improved. He attended school for two days and returned home with a temperature of 101 F, with severe pain over his right eye, and earache. His mental disturbances returned. He had difficulty in walking and insisted that the roof was falling in on him. At this time, a mastoidectomy was performed.

There was an area of dura in the middle fossa one-half by one-fourth inch wide exposed which was markedly inflamed. The overlying bone bled freely. The mastoid cells were filled with purulent debris and, at the time, I thought that this dural irritation might account for some of his symptoms. The headache persisted however, requiring frequent hypodermics of one-half grain (0.03 Gm) of codeine to control it. Five days following the mastoidectomy he had what his mother described

as a "fit." He had a marked photophobia and a diplopia, and was unable to differentiate various objects in the room. He was extremely dizzy, had loss of appetite, vomited frequently and had a rotary nystagmus counterclockwise; there were 15,000 leukocytes. The eyegrounds were normal and there was a moderate weakness of the right external rectus muscle.

Six days following the mastoidectomy, his brain in the region of the middle fossa was explored, but no abscess was located. A rubber catheter drain was inserted and I contemplated a later exploration of the cerebellum. Three days later there was a sudden discharge of pus through the drainage tube, and the patient promptly was much better. Within four days the drainage had all stopped, the patient seemed normal in every way, and he was dismissed one week later.

This patient again illustrates the relation of the chronic ear infection to brain abscess, the rather obscure early symptoms, the more or less accidental

Fig 3 (case 4)—Cross sections of brain through the fourth, sixth, and eighth layers showing the extensive abscess formation and rupture into the ventricles.

drainage of the abscess, and the advisability of waiting between brain operations in the hope that the abscess may reach the drum

CASE 6—G E, a girl, aged 11 years, was brought to Mercy Hospital on account of severe headache and inability to walk without falling forward Five years before she had had a severe earache, following an attack of influenza, at which time her ear did not drain, but the mastoid process became swollen, red and tender, and the mother was advised to have the child's mastoid process operated on

This swelling gradually subsided, and she had no more ear trouble until Christmas, 1926, two months prior to the hospital admission Following a cold, she had a severe left earache, and, for the first time, the ear started to drain This gave her only temporary relief, however, as she developed a severe frontal headache which was continuous and kept her awake nights Gradually this subsided Three weeks later, while returning from school, she was drenched in a rain storm Following this she had a hard chill with a high fever, projectile vomiting and a return of her headache The ear continued to drain but did not cause pain

On admission to the hospital she was only semiconscious She fell forward when she attempted to walk, and had a marked photophobia, the pupils were widely dilated, and it was difficult to arouse her She groaned continuously and would scream out occasionally and beg to be relieved of the pain over her eyes

Her diagnosis was so obvious that the admitting nurse told me I had a patient with a brain abscess in my service With the typical ear history the location was not difficult to surmise

A simple mastoidectomy was promptly done The cortex was thick and hard and prevented external drainage The entire mastoid process was filled with a pulsating abscess under distinct pressure The floor of this abscess was the dura covering the sigmoid and was covered with dense, fibrous tissue indicative of an old process So much pus was found, and the patient improved so promptly when the abscess was drained, that I thought it probable that I was dealing entirely with an extradural abscess

The child made all the characteristic postoperative brain abscess improvements, except one she still had her severe frontal headache I was called out of the city for twenty four hours, and, when I returned I found my patient in exactly the same condition as on admission

She was returned to the operating room, and a small abscess was drained directly beneath the lower third of the sigmoid About 2 drachms (8 cc) of light yellow pus was found There was no improvement, and further search for another abscess was continued until the patient's condition became so grave that it was thought inadvisable to continue In desperation a rubber catheter was dropped into the cerebellum through a small incision in the dura of the posterior fossa The mastoid wound was lightly packed, and the child was returned to her room in about the same condition as that in which she had left it

That night her condition became so serious that oxygen was administered The respiration slowed to 6 a minute She could not be aroused Imagine my surprise when I found her the next morning eating breakfast with a ravenous appetite entirely unaware of her recent experience!

The night nurse said that about midnight she noticed that the mastoid dressings were saturated with pus and that the patient suddenly began to breathe more normally that the pulse increased in volume and rate and that when the patient awakened at 6 30 a m she asked for food Her headache had also disappeared

When I changed the dressings about the ear I noticed that a large amount of foul smelling pus had completely saturated all the gauze and had drained out on the pillow From the catheter which I had inserted into the cerebellum thick, greenish yellow pus was oozing forth This was aspirated, and the abscess was gently irrigated with Asch's solution without moving the tube A considerable amount of pus was washed out

Except for a paralysis of the external rectus muscle of the left eye, the patient was normal in every way and continued to make rapid progress On the sixth day after the operation

while I was irrigating the abscess for the last time (since the washings were clear) the patient suddenly screamed, "Oh, my head" and, grasping the top of her head with her hands, fell backward on the pillow and was apparently unconscious

I did not attempt to arouse her but immediately wrote on her chart that I had killed my patient by rupturing the capsule of the brain abscess at a time when she had apparently recovered I had noticed that the fluid did not return promptly about the catheter on account of the narrowing of the fistula, and, although I was using a 30 cc syringe, I thought that I was not exerting enough pressure to cause harm

After returning to the office I was so depressed and worried that I did not care to see patients with minor ills, so I returned to the hospital There she was sitting up in bed cutting out paper dolls, and in spite of all my questions and suggestions she would not admit that there was anything wrong Her convalescence has proved that she was correct, and her left eye has regained its normal movements

An additional point of interest was the complete amnesia which she had from Christmas until her brain abscess was drained This was demonstrated by her own observation that she could remember nothing about a serial motion picture from Christmas on although she missed only one night

She has done so well in school that a grade has been skipped and her weight has increased 30 pounds (14 Kg)

This case illustrates the danger of postoperative interference in brain abscess Irrigations are unnecessary and there is danger of rupturing the abscess wall

and producing a diffuse meningitis. The favorable result here might be classed as an accident, but it demonstrates the advisability of inserting a blind drain, even though no abscess has been reached.

SUMMARY

During a recent visit to some of the Eastern hospitals, I was struck by the indifferent attitude of the otologist to the patient with a brain abscess. Once the lesion was diagnosed, the patient was promptly transferred to the neurologic service, where he was not seen again by the otologist. It was my impression that the brain abscess patient was shifted and transferred as much as possible from one service to the other because of the attitude expressed by the attending intern at one hospital in the words "I heartily approve of transferring these patients as all of our patients who develop brain abscess die anyhow."

It is, I believe, the fatalistic attitude toward this lesion which is so destructive to any progress in the proper management. One also frequently hears of the recurrence of this lesion and of the mental impairment which these patients afterward suffer. From experience with my own patients, and in reading of others, I am convinced that the patients who have completely recovered from a brain abscess suffer no more impairment after the operation or recurrence than patients who have had an appendectomy. One has only to see such skilful surgeons as Cushing and Dandy operating on the brain for the removal of tumors to realize how much may be done to this organ without disturbance of function.

After all, it does not matter so much who performs the surgery on the brain abscess, as the fact that it must be recognized early enough to afford an opportunity for proper surgical procedure. Failing, as it does so frequently, within the field of the otologist, it behooves him to be familiar with the clinical course of this lesion and to realize how frequently brain abscess exists as a complication of ear infection.

902 Medical Arts Building

ABSTRACT OF DISCUSSION

DR R. BISHOP CANFIELD, Ann Arbor, Mich. In our last series of forty-two cases at the University of Michigan Hospital, otitic suppuration was by far the most important single factor, being important in 38 per cent of the total number. The question occasionally arises as to whether in a given case of otogenous brain abscess it is better to eradicate the suppurative otitis media and then to attack the brain abscess or to reverse the procedure. In this connection it must be borne in mind that a previously active but apparently healed otitis media is of but slightly less clinical importance than a suppurative otitis media, active at the time of observation. While I agree with Dr. Dixon that failure to recognize the presence of the abscess at the earliest possible moment is regrettable, I feel that careful consideration must be given to the selection of the most favorable time for operation. I am by no means of the opinion that the operation should always be made as soon as the presence of the abscess is recognized. While it is fatal to delay intervention until a leptomeningitis has been established, it is unwise to intervene during the acute stage, during which the condition is essentially a progressive acute encephalitis. Intervention at this time is likely to bring about an extension of the encephalitis and to set up a leptomeningitis. It seems wiser to wait within reason for the attempt on the part of nature to form a limiting membrane around the focus of infection. The chief problem that the otologist faces is whether he shall approach the abscess from the mastoid or through the neighboring part of the skull. This question should be decided at

the operating table and in accordance with the conditions found in each individual case, three important points being borne in mind: 1. Opening the brain from the infected mastoid cavity may establish a meningitis when no definite track of infection can be demonstrated. 2. Abscesses lying deeply beneath the cortex must be made superficial before successful drainage can be maintained. 3. The abscess that can be drained most successfully is the one that is reached by a path extending at right angles to the skull. In general I agree heartily with the precepts laid down by Dr. Dixon.

DR FRANCIS V. GOWEN, Philadelphia. Barany stated that at the beginning of the war the Germans and Austrians lost most of their brain abscess cases as the result of packing the abscess cavities with gauze. This gauze, instead of aiding in the removal of the pus, merely became saturated and acted as a cork, preventing efficient drainage, and in addition caused it to burrow back along the course of the nerve fibers, thus causing dissemination of the pus and eventuating in a generalized encephalitis. When they changed to the other method they reversed the figures and most of the patients were saved. The newer treatment consisted in making a wide incision into the abscess cavity, gently irrigating the pus contents from the lowermost depths, separating the lips of the wound widely and using head mirror reflected light so the operator knew when he reached the bottom of the wound. After complete examination the lips of the wound were kept apart with glass or non-corrosive metals or steatophil paper, and the patient's head placed in favorable position for the continuous flow of drainage. This treatment was given two or three times a day. The fact that it is important to see to the bottom of the abscess cavity necessitates the use of a head mirror, and since a head mirror is an unwieldy object except in the hands of one accustomed to its use, one might conclude that otitic brain abscesses are best handled by the trained otologist.

DR E. LEE MILES, St. Louis. I have had only about eleven cases. I am not counting extradural and subdural abscesses, in which I believe most operators get good results. As I remember, the only patient that got well was a child that had a Bezold abscess. There was terrific swelling, and as soon as the cortex of the mastoid was uncovered a cavity was entered that was so deep that I did not dare do anything. I have seen this child grow up. I cannot say I am satisfied with the result because the child is not normal mentally. I do not know what she would have been if she had not the mastoid condition. The other children are well poised mentally. Of cerebral abscesses I have had about ten, and every patient died. One case was a multiple brain abscess, in which there was cerebral and also cerebellar abscess. I have recently had a case which has disheartened me. A child in less than a week after I had removed the adenoids started to have a fever but no chills. I did a jugular sinus ligation on the right side, and a short time afterward the child had more fever and I opened the lateral sinus on the other side. I had the characteristic swelling of the optic disk, and in four or five days the child developed a nystagmus to the right and a meningeal cry. This child gave me trouble for three or four months, but finally she got out of bed, with this terrific swelling of the optic disk, and went back to school and seemed to be normal. A year afterward the child seemed perfectly normal except occasionally for a little nystagmus. Three or four weeks prior to that time the mother called my attention to the fact that the child had slight headaches. I put her through tests and could not find a cerebellar syndrome, and sent her to a neurologist and he said that the baby was perfectly normal. This child was brought back later with explosive vomiting, but two celebrated neurologic surgeons could not find what the trouble was. I turned the patient over to a general surgeon and he found a right cerebellar abscess. In three months the child developed meningitis. In other words, the child lived fourteen months after the first mastoid operation was done.

DR J. B. PORTS, Omaha. I have to differ with the author as to the neurologist. After having worked with one for a considerable time I feel that he is the best adviser I have. He does not hesitate to advise operation and he does recognize

brain abscesses of otitic and sinus origin. If one must have a consultant who is not used to ear, nose and throat work, I agree with the author that he can be a hindrance rather than a help. In regard to quoting statistics from foreign clinics, I think one has to be a little careful because there is a larger population to the physician than in this country, and more neglected ears than are found in the general practice of the otologist in the United States. I want to commend the author's approach to the abscess. I told this point over with the neurologist I work with at home, and with a neurologic surgeon, and they both agreed that in all cases of brain abscess the best results were obtained when the abscess was opened with the least trauma to the brain. In other words, if a small opening is made into the dura and the abscess is found at the first puncture, the drainage tube introduced without plunging around in the brain and without introducing a knife or needle two or three times, and the tube removed gradually, such cases do the best, so I would heartily commend the suggestion that the least possible trauma be done to the brain. I have no quarrel about the different types of drainage. I use a type similar to that the author mentioned, except that I remove the rubber tube fairly early and use in its place a silver wire loop. In regard to early drainage in talking with various men who have operated on brain abscesses I have found that all have observed that in the early cases in which the abscess was not walled off the danger of losing the patient was greater.

DR JOHN F. BARNHILL, Indianapolis. In typical cases of brain abscess, the diagnosis is often easy. In atypical cases, such ease may not be expected. The symptoms on which diagnosis is based, as outlined by Macewen many years ago, are applicable to the typical, uncomplicated case and are of little or no help in others. To depend on slow pulse, slow respiration and subnormal temperature in all cases will lead the surgeon widely astray in many instances, for, in addition to the abscess, the patient suffers from meningitis, either local or general, increased pulse rate, rapid respiration and elevated temperature are usually present even though the brain abscess is large. Macewen's list of symptoms is therefore no longer useful and others must be depended upon. The history of the case, the pathologic condition found in the ear at examination, the condition of the bone found on mastoid operation if operation has been performed, are all suggestive and helpful. Papillitis or papilledema will be found usually, but often only after repeated examination. It is a symptom of intracranial pressure and therefore does not occur until such pressure is considerable. My chief point is, the unreliability of Macewen's series of symptoms in atypical brain abscess.

DR HAROLD M. HAYS, New York. I should like Dr. Dixon's opinion about a certain type of case which is seen infrequently. I will illustrate by two typical examples. A number of years ago I operated on a youngster for a double mastoid condition. The recovery was more or less uneventful. At the end of three weeks she developed a high temperature and every symptom of meningitis. Spinal puncture showed fluid at a great pressure and very cloudy. The opisthotonos was so great that the head almost touched the heels. I returned her to the hospital again, a consultation was held and a diagnosis of acute meningitis was made. The prognosis seemed hopeless. However, I decided that it would do no harm to reopen the wounds and to uncover the dura. On the following day the child's temperature had dropped, she was conscious and sitting up in bed, and at the end of one week she went home entirely recovered. In the second case, a typical textbook operation on the mastoid was performed. On the fourth day the patient complained of excruciating pain in the middle ear. The temperature was 104 F and signs of meningeal irritation arose. Spinal puncture showed fluid under slight pressure and clear. Consultation was held and a hopeless prognosis given. Because of the recovery in the previous case, I decided to uncover the dura. This was done and the following day the temperature became normal and the child recovered. Recently I had a patient referred to me who had been operated on for mastoiditis by a competent man. When I saw the child a few weeks after operation, I found a healed wound but suspected

some complication. I referred her to the hospital, where she remained for almost a week with a normal temperature and seemed well enough to be discharged as cured. A week later she developed a sudden high temperature and every sign of meningitis. She was not under my care at this time, but on being called in consultation I advised uncapping the dura. However, this was not done and the child died. Whenever patients have complicating elevations of temperature and symptoms after acute mastoid operations there is a possible localized infection in the dura or an epidural abscess and frequently recovery will take place if the dura is uncapped.

DR O. JASON DIXON, Kansas City, Mo. Regarding Dr. Myers' patient I had a similar case which emphasizes the importance of looking over the nurse's record. The nurse often is describing a case of brain abscess, although she is unaware of the condition. Unbiased observations may be extremely valuable, and I always encourage the nurse to write down every detail, such as disorientation, vomiting, the patient's remarks, and what she thinks of the patient's progress. Of course, mistakes will always be made in the differential diagnosis of brain abscess, particularly in tumors and especially in tuberculous meningitis. I have recently explored the brains of three children with septic ears, who had tuberculous meningitis. That is one of the most confusing complications. A patient with a tumor case whom I had prepared for operation suddenly developed a high temperature and convulsions and died. I had diagnosed a brain abscess and thought that I had waited too long. At necropsy we found the tumor, so I was wrong on that. Neurologic consultation may be of great help, but one individual must accept the responsibility, and he should be the surgeon. If the responsibility is divided there will not be any action. Regarding the possibility of differentiating between acute and chronic brain abscess, that is really a difference in the pathologic changes. I am convinced that a higher percentage of good results in brain abscess would be obtained if the patient did not die of the meningitis which they all have during the early stage of development. Unfortunately, they do not all have just a pachymeningitis but a diffuse meningitis, and they die before the abscess has time to form. The abscess is really the end result and is not the primary part of the disease. I have had the same feeling as Dr. Barnhill about choked disk. I do not pay much attention to it. If I cannot see it, I let it go. Visual fields help if the patient is in a condition to cooperate. The case that Dr. Hays had I would interpret as pachymeningitis with irritation around the dura of the middle fossa. In practically every mastoidectomy with streptococcal infection I uncover the dura. I think that this is one stage of a brain abscess, but few go on beyond the pachymeningitis. It must constantly be borne in mind that patients with brain abscess may conduct themselves in a fairly normal manner.

Streptococci and Rheumatism.—To summarize the bacteriologic views of the moment, it would be correct to say that the close relationship of streptococcal infection and acute rheumatism is again receiving much wider recognition although the exact cause of the disease still remains in doubt. The protagonists of the streptococcal theory of rheumatism are roughly divided into two groups—those who believe in a specific streptococcus and those who imagine that various streptococci are capable of producing the disease. The organism, which has been isolated by most investigators from the blood and various lesions in rheumatic patients is a *Streptococcus viridans* although on several occasions hemolytic streptococci have been reported. In 1927, a separate effort was made by two different observers, Birkhaug and Small, to establish another distinct streptococcus as the cause of rheumatism. Small called his organism the *Streptococcus cardio-arthritis*, whilst Birkhaug not venturing on a name, designated his as a new type of non-methaemoglobin forming streptococcus. During the last few years almost as much work has been done to show that no single type of streptococcus is exclusively responsible for rheumatism as previously had been expended in proving the opposite.—PONTON F. J. and SCHLESINGER BERNARD. Recent Advances in the Study of Rheumatism, Philadelphia: P. Blakiston's Son and Co. Inc., 1931.

INTERTROCHANTERIC FRACTURE OF THE FEMUR*

S POTTER BARTLEY, MD
BROOKLYN

My purpose in this paper is to review 100 consecutive fractures of the femur occurring in adults and to describe in detail the method of management in intertrochanteric fractures which, in my experience, has given the best end-results

Intertrochanteric fracture, as the name implies, is that fracture in which the plane of bony separation extends from the greater trochanter downward and through the lesser trochanter. This fracture should not be considered as a fracture of the femoral neck and should not be included in the consideration of fractures

Fig. 1—Comminuted and impacted intertrochanteric fracture with separation of the lesser trochanter

of the neck of the femur. This is mentioned because in not a few papers and in the clinical demonstration of fracture of the femoral neck, intertrochanteric fracture is at times included. It might also be stated that in a review of roentgenograms, intertrochanteric fractures are classified as fractures of the neck of the femur in many instances.

The anatomic varieties of this fracture are fairly constant. Most of the fractures are comminuted and frequently impacted (fig 1). However, at times the fragments are separated and the hip angle is reduced from normal (which can be considered 130 degrees) to a right angle or less (fig 2). This produces varying degrees of shortening. Rotation of the distal shaft is infrequently seen. Intertrochanteric fractures are at

times accompanied by subtrochanteric fracture lines, running longitudinally into the shaft of the femur in the subtrochanteric region (fig 3). Comminuted lines of fracture running into the femoral neck from the intertrochanteric region are not seen (fig 4).

A compound fracture in this region is extremely rare, in fact, it is almost impossible for compounding to be produced, owing to the protection afforded this particular area.

A review of my experience with 100 consecutive cases of fracture of the femur in adults shows that 18 per cent of the femoral fractures were of the intertrochanteric variety. Other observers, such as Speed, state that 24 per cent of all fractures of the femur are intertrochanteric in location. The average age of the patients in my series who sustained this fracture is 58 years. In the series reported by Speed, the average age was 60. There is apparently a greater predominance of this type of fracture in men. It is practically unknown in childhood and rare in young adults, except after great violence.

It seems, therefore, that the predominance of this type of fracture in people past middle age is due to the amount of bone atrophy that is commonly present in the older patients. The age of the majority of the patients acquiring this fracture and the anatomic relationship in this location are predisposing factors in the rather high incidence of pathologic fractures due to metastatic carcinoma and bone cysts (figs 5 and 6).

COMPLICATIONS

Local complications involving the fracture itself are uncommon. Those frequently encountered are due to the general condition and age of the patient, such as varying degrees of shock, cardiovascular lesions and pneumonia of the hypostatic or bronchial type. Nonunion practically never occurs. This is an interesting observation and in all probability is due to the excellent circulation that occurs in the bone at this point, as all branches of the nutrient artery of the shaft terminate at about the intertrochanteric line. Just above this line, in the neck of the femur, the reverse situation anatomically is present in that the circulation is extremely poor and there is a very high incidence of nonunion in neck fractures.

The age of the individual seems to have little or nothing to do with the union, since elderly patients repair intertrochanteric fractures with the same rapidity and completeness as do the younger individuals. On the other hand, in fractures involving the neck of the femur, age is supposed to be the greatest factor in nonunion. This is rather difficult to believe since in patients of the same age union occurs so rapidly in intertrochanteric fractures, as compared with fractures of the neck. The period of time necessary for bony union to occur in intertrochanteric fracture of the femur in patients whose average age is 60 is from six to eight weeks.

The mechanism responsible for intertrochanteric fractures can be briefly stated as follows. The patient usually falls backward or to the side, striking the trochanteric region directly on the ground. To resist this fall he usually holds the thigh in abduction and external rotation by the contraction muscles attached to the greater trochanter. In this manner he receives a fracture extending from the greater trochanter downward and through the lesser trochanter, usually impacting the fragments of the trochanteric region into the cancellous bone of the distal shaft. Complete separation

* Read before the Section on Orthopedic Surgery at the Eighty First Annual Session of the American Medical Association, Detroit, June 26, 1930.

* Owing to lack of space this article is abbreviated here by the omission of several illustrations. The complete article appears in the author's reprints.

of the fragments may occur with backward sliding of the shaft toward the brim of the acetabulum

DIAGNOSIS

The diagnosis of this type of fracture is in part made on the history of the patient's falling in the manner just described. Usually he is unable to walk on the injured extremity and the disability is more or less complete.

In some, but not all, patients, the limb is shortened but not to the extent that is encountered in fractures of the femoral shaft. The foot is usually not everted as is frequently noted in fractures of the neck of the femur or dislocation of the hip joint. The axis of the limb is not visibly out of alignment excepting in those complete fractures in which adduction is present, with a decrease in the hip angle. Crepitus is usually present except in those fractures which are impacted. This is due to the fact that a large percentage of the fractures are comminuted. Adduction and rotation, if attempted, are always painful.

The maximum point of tenderness is located over the greater trochanter, outside the femoral head and neck. The relationship of the upper border of the trochanter to Nelaton's line is not changed in most cases unless the trochanter is displaced well upward, which is not a frequent occurrence. I therefore believe that this sign, often stressed in the diagnosis of this fracture, is of little importance. Roentgenographic study of the region of the hip either confirms or refutes the diagnosis made on clinical observations.

TREATMENT

The treatment of the patient suffering with an intertrochanteric fracture may well be divided into two parts.

1 A careful survey of the general condition of the individual. This is of extreme importance in this instance because of the age of the patients. Shock, cardiovascular complications and pulmonary complications are not uncommon and may often be prevented by a familiarity with the general condition of the patient and by the institution of prophylactic treatment soon after the injury. Anesthesia in patients of this type is to be avoided whenever possible and treatment planned to give the shortest period of bed confinement and the least restriction of motion, particularly of the knee joint. Apparatus should be applied which will give comfort to the patient, permit him to assume the sitting

position and allow for early massage of the limb involved.

2 Treatment of the local condition. In my opinion the form of treatment which most nearly meets the foregoing indications is that of traction with suspension and abduction of the limb. This treatment is applied as a routine in all intertrochanteric fractures excepting the incomplete fractures without separation of fragments. In such instances the patients are simply kept in bed, perhaps with the limb supported with sandbags, for a period of three weeks. During this period heat in the form of infra-red rays and massage are applied daily. This procedure seems to diminish the pain at the site of the injury and to increase the resolution of swelling. Weight bearing is not allowed for from six to eight weeks after the injury and then only with the aid of crutches. The patient is permitted to walk without support at the end of three or four months. During this later period the massage is continued and active exercises, particularly abduction and rotation, are indulged in by the patient. Complete fractures usually present the following deformity for correction: 1 Shortening 2 Decrease in the hip angle 3 Adduction. It therefore follows that any form of treatment applied must be capable of completely correcting these anatomic conditions. This is accomplished by traction and countertraction in suspension, with the leg in abduction and with the knee and hip joints moderately flexed, the limb thus being in a position of neutral muscle pull.

Traction on a fully extended limb is to be condemned, as in most instances it will cause considerable difficulty

Fig 5—Metastatic carcinoma of the femur with spontaneous fracture (Carcinoma of breast)

with the knee joint and will not be nearly as effective in reducing the deformity as traction applied in the position of neutral muscle pull. Another method to be condemned is that in which so-called temporary splints are applied, causing delay in the reduction and permanent immobilization. Traction should be applied as soon after the injury as possible. The earlier it is applied the easier will be the reduction and the sooner

will pain be controlled, a factor of considerable importance in these elderly individuals in the treatment of any shock present and in the care of their general condition.

The apparatus applied is a wooden adjustable bed frame (fig 9). A Thomas ring splint with flexion knee piece is attached. The foot of the bed is elevated to prevent pressure on the perineum, the ring of the splint is bent to rather an egg shape to relieve any pressure in the trochanteric region which is apt to be present when the leg is swung into position of abduction.

Fig 9—Traction apparatus showing splint and frame in place

Traction is important. In most patients the two plane type of traction, using adhesive plaster, is applied. This is applied with the knee and hip flexed and the foot kept at a right angle or in slight dorsal flexion. The amount of weight used in this type of traction is usually about 15 to 18 pounds in each plane of traction. Following this the patient is kept free from pain by the use of morphine and the weight is reduced as soon as the shortening is overcome. This is determined by simple measurement of the legs by means of steel tape. This method is far superior to the frequent measurement and gradual increasing of weight to obtain reduction or shortening.

Traction is applied without abduction at first until the shortening is overcome, as it is found that this is more rapidly overcome in the straight extended position than in the position of abduction. As soon as shortening is no longer present, the splint is swung out into as much abduction as possible.

A bedside roentgenogram is then taken and if difficulty is encountered in maintaining enough abduction to overcome the loss of the normal angle between the neck and the shaft, the opposite limb may be placed in the same position, or an adjustable pressure pad may be inserted over the greater trochanter, giving a fixed point on which to abduct the lower fragment.

In a few cases the shortening may be considerable and the hip angle much reduced. If this occurs in a young individual with heavy musculature of the thigh, ice-tong calipers should be applied rather than any type of adhesive plaster traction. Direct bone traction in this manner can be used with uniform success in all intertrochanteric fractures in which shortening is present, as the results are satisfactory. However, I do not feel that it is necessary except in a few selected cases.

The apparatus is left in place for periods varying from five to seven weeks and the patient allowed to move the knee joint after two weeks of immobilization.

Massage to the intertrochanteric region and muscles of the thigh, together with the application of heat, is of considerable value in producing comfort and in maintaining the best possible condition of the musculature.

Beside roentgen examination, together with clinical examination by manual attempts to move the trochanter in the anteroposterior plane and the amount of pain present on these attempted manipulations, are the guides in determining the amount of union present.

When from roentgen and clinical examinations union is known to exist, all apparatus is removed and the patient is allowed simply to lie in bed for a period of two weeks. During this period more active physical therapy is instituted, particularly that of active motion of the knee joint. The patient is then allowed up and about with crutches and a well fitted caliper walking splint. The use of a walking caliper splint is essential in these patients, as the earlier they are allowed to walk, the shorter will be the period of disability. While union in these fractures readily occurs, it has been found that complete repair of the fracture is at times delayed and if weight bearing is allowed under such circumstances, angulation at the site of fracture is very apt to occur, with a resulting *covr vara* deformity.

The patient is then ready to be discharged from the hospital and as an ambulatory patient is given physical therapy three or four times a week. This physical therapy consists of infra-red irradiation or diathermy applied to the intertrochanteric region and hip joint, together with massage and active exercise of the knee and hip. Abduction and rotation are particularly important in this type of fracture.

The ambulatory splint is worn until the union has progressed to the point at which weight bearing without support seems safe, in uncomplicated cases about the end of the fifth month.

The other method of treatment that I have used in the management of these fractures is manual reduction with the aid of a mechanical table and the application

Fig 10—Method of applying two plane traction

of a plaster-of-paris spica in abduction with slight internal rotation. To do this, in most instances, general or spinal anesthesia is necessary.

The disadvantages of this method over the method by traction as described are the necessity for some form of anesthesia and a more rigid immobilization of the entire patient, the lack of ability to sit up in bed, with its consequent predisposition to hypostatic pneumonia and bronchopneumonia, the inability to apply any form of physical therapy to the musculature of the leg, the rigid immobilization of the knee joint which, in

people of this age, is a serious matter as far as future function of the joint is concerned, and the extended period of disability because of the prolonged treatment of a stiffened knee joint. The condition of the knee joint, in most instances, is more of a surgical problem than the intertrochanteric fracture.

The advantage of the method is that it enables one to effect a more perfect immobilization of the fracture line and maintain a greater degree of abduction, neither of which is especially important or worth the disadvantages of the method.

Open operation is indicated when the type of treatment described fails to produce reasonable anatomic reposition of fragments compatible with good function. In my experience, this indication has never arisen. Operative removal of projecting bone fragments may be indicated if the displacement is great enough to cause disability.

PROGNOSIS

If the patient receiving an intertrochanteric fracture of the femur survives the initial shock of the injury, recovery will ensue with a minimum loss of function and more satisfactorily and rapidly than from other types of fracture of the femur.

Fig. 11—Ambulatory splint

As nonunion is rare and the reduction of the deformity easily obtained, the prognosis in intertrochanteric fracture is good. The period of total disability rarely exceeds from six to seven months and the period of partial disability may continue for another month or six weeks. In the industrially injured, the period of disability is much longer. This is not unusual in this type of patient, as the disability is complicated by so many other problems than the fracture itself. For this reason any estimate as to the exact period of disability is without value.

In the industrially injured whom I have treated the average time between the injury and the date of return to occupation has been one year. In the same series, however, the average disability of patients not under compensation laws has been from six to seven months.

To state that patients with intertrochanteric fracture recover without any permanent functional loss is indeed an error, as nearly all have some permanent limitation of motion of the hip joint. The most notable limitation is that of abduction. In the industrially injured going before compensation boards, the average estimated permanent loss of function of the leg involved is much greater than is commonly supposed. The exact cause of the permanent limitation of motion is not clear. From a study of 100 patients examined from one to three years after injury, clinical and roentgen examina-

tion of intertrochanteric fractures shows that nearly all have some intra-articular hypertrophic change, although in no instance was the fracture line seen to enter the hip joint. Shortening of the abductor muscles of the hip was also a rather common finding in those patients with limited hip motion.

The question of function of the knee joint in these patients depends on many factors. In some of the patients, varying degrees of permanent loss of flexion have been found. In one or two instances, flexion of the knee was limited to a little better than a right angle. In the majority of patients, however, the permanent loss of function was from 10 to 15 degrees of flexion.

The patients in whom permanent knee joint involvement has been found are those who have been treated with a plaster-of-paris spica for immobilization. The age of the patient is also recognized as a factor in permanent loss of part of the function of the knee joint.

The mortality rate is low. In the patients studied in my series there were no deaths from intertrochanteric fracture, although the average age of these patients was much higher than in patients with fractures of the femoral shaft and almost equaled the average age of patients with fracture of the neck of the femur.

The prognosis then seems to depend for the most part on the protection given the patient's general condition, the avoidance of anesthesia and the early immobilization of the joints, which from my experience is best obtained by the routine use of suspension and traction in the treatment of intertrochanteric fractures.

164 Clinton Street

ABSTRACT OF DISCUSSION

DR KELLOGG SPEED, Chicago. There are three more points about intertrochanteric fractures. They occur in elderly people, a bony union is sure to follow if the patient survives, and the mortality is rather high. Dr Bartley mentioned that this fracture was not a fracture of the neck. It is not a fracture of the femoral neck. The symptoms and physical signs are decidedly different from those of the neck. The amount of impaction is usually striking. The amount of shortening is small and the patient may have so few pronounced symptoms that the fracture itself is overlooked at first until a roentgenogram is made several days or even weeks after the fracture has occurred. I don't see how it can be clinically confused with the dislocation of a hip, especially the ordinary posterior dislocation. Certain visceral symptoms accompany these fractures, namely, blood in the urine and in the stools and the development at times of a mild paralytic ileus. These symptoms are probably induced by the mechanism of the fracture that is by the force resulting from that mechanism, the smashing blow on the hip transmitted to the pelvis and the pelvic organs as in those central fractures of the acetabulum in which the head is pushed through into the pelvic cavity. In a certain percentage of these cases the early and alarming symptoms are directed toward these visceral upsets. I have no brief for the plaster-of-paris dressing in this particular type of fracture because, after all, the dressing that gives satisfaction is the one to use, however, if suspension traction fails to restore the neck angle, it may lead to certain things, particularly to *convexa* and to the formation of excess callus. The cases of most pronounced excessive callus I have ever seen have followed intertrochanteric fracture when the fracture was not reduced, the angle was not restored and the scattered fragments, the large open cancellous bone surface, led to a large formation of new bone.

DR HERBERT C FETT, Brooklyn. The treatment of the patient is most important. As Dr Speed said, if the patient gets well the fracture will get well. Early recognition and the institution of early treatment are important. The early treatment is so important that many of the hospitals are today regarding fracture as an emergency. I was surprised to hear

Dr Bartley say that he started weight bearing between the sixth and the eighth week on the patients who had the split fracture. This seems to me to be somewhat early. I should prefer to keep these patients from weight bearing for at least three months. I was happy to hear Dr Bartley say that he is getting away from the use of plaster of paris in these cases and it is my opinion that one has considerably more trouble with the knee joint subsequently than one does with the fracture itself. His form of treatment is very satisfactory, particularly in view of the fact that an anesthetic can be avoided in the older people. The last point I should like to bring out is the fact that I prefer to use the Steinman pin for the cases in which the fracture will not reduce rather than calipers, because of the possibility of calipers moving and also the possibility of infection.

LUNATE OSTEOMALACIA*

EDWARD S. BLAINE, M.D.
LOS ANGELES

A peculiar lesion of the lunate or semilunar bone of the wrist is being encountered with increasing frequency, a fact that has stimulated the interest of a number of roentgenologists and is the incentive for this presentation. Having encountered several of these cases, I present the results of a study of various factors in this unusual lesion.

Kienbock,¹ in 1911, first described the roentgen observations in this condition, and on this account the lesion is frequently called "Kienbock's disease." Kohler,² in his book on roentgenology, prefers to call it "secondary post-traumatic malacia." Others, among them Baum,³ Frenkel-Tissot,⁴ Hering,⁵ Kautz,⁶ and Henderson,⁷ have written on the subject using variants in terminology according to their individual points of view as to causative factors and pathologic conceptions. This lack of uniformity of terminology is tending to some confusion in classification. At the present moment authorities are not agreed on several of the aspects of the case, particularly the etiology. Thus, a division of opinion finds one group of observers which consider the condition to be due primarily to a trauma, while another group believes it to be nontraumatic in origin, with an incidental fracture occurring in some of the cases in a later stage of the disease process.

The roentgenologist's attention is directed to the condition by the roentgen finding of a faulty shadow detail of the semilunar bone in certain wrists, some with and others without injury. This abnormal appearance may be merely a fault in shape and size, or it may be a fault in bone detail, or both. A decrease in the size of the lunate bone is sometimes the only change noted. In the advanced case the normal, spongy or cancellous architecture is replaced by an apparently disintegrated bone showing ill defined margins and increased radiability—often with an osteoporosis that is quite marked.

A prominent feature in most of the cases reported in the literature is an insidious onset without sudden or severe injury, sometimes none at all, and a relatively long period of development of the lesion and the tardy appearance of the symptoms. Thus it has been found that, immediately after an injury relatively inconse-

quential, the roentgen shadows of the bones of the wrist are those of entirely normal carpal bones for a matter of several weeks. Because pain and disability still continue, roentgen study, made from several months to a year later, reveals a striking change involving only the lunate bones, the principal features of which appear to be those of a bone necrosis.

Those who regard the condition as the direct result of trauma divide these cases into three groups: (1) those due to the abnormal anatomic conditions incident to the lunate bone, (2) those due to occupational trauma in the form of repeated compression strains, and (3) those in which a single severe compression force initiates the disease.

Many observers consider the changes that characterize Kienbock's disease as due to a shutting off of the blood supply to the semilunar bone, as a result of which a nutritional starvation of the bone occurs with resultant softening, necrosis and disintegration.

In the early stages of the nontraumatic form there is a relatively slight disability and slight pain for a short period, then follows a period of relative absence

Fig. 1—Left and right carpal regions in case 1 showing a normal left and a pathologic right lunate bone—typical shrinkage characteristic of the lesion.

of symptoms lasting from several weeks to several months, and this is followed by a third stage, in which the symptoms return, greatly accentuated. After a long period of time, usually with indifferent success in treatment, the symptoms may subside, but the recovery process is extraordinarily slow and the disability is considerable. The roentgen observations are practically unchanged even long after symptomatic recovery. In a few cases an osteosclerosis of the altered lunate bone was disclosed as an end-result.

Kappis⁸ reports the microscopic observations in a case of malacia of the lunate bone in which there was a complete necrosis of the spongiosa and of the bone marrow.

It has been suggested by some observers that an embolic obstruction in the arterial supply to the semilunar bone is the cause of this lesion, the clot having resulted from a minute fracture, but many investigators question this hypothesis. Others call attention to the anatomic position and relatively poor blood supply of the semilunar bone, offering these as factors in the

production of the softening process that is found both roentgenologically and microscopically

In some of the cases the roentgen shadows failed to reveal a fracture that actually was present, the failure being due to the transverse direction of the line of cleavage to the postero-anterior projections and the difficulty of visualizing the minute detail of the several superimposed carpal bone shadows on the lateral projections. In a number of cases it was only after pressure absorption on the apposing fracture surfaces took place that the shadow of the fracture line appeared on the later roentgenogram, the original roentgen studies failing to show a fracture. In a number of the cases cystic changes appeared to be a predisposing cause for Kienbock's disease. The minute fracture through these tiny cysts, which most roentgenologists of large experience have seen many times in carpal bones, seem logically to be a predisposing cause for the changes that characterize this lesion. One is impressed with the similarity of the changes in post-traumatic malacia of the semilunar bone and those of post-traumatic vertebral collapse, or Kummel's disease.⁹ It seems logical to assume that since the factors of etiology, symptomatology and pathology are more or less identical in these and in similar lesions that are found to involve various osseous structures of the body, they are all essentially the same lesion. Some observers include in this category Kohler's disease of the scaphoid, but Kohler himself specifically disagrees with this hypothesis.

A noteworthy point is the relative frequency of mistaking this lesion for an acute injury when the roentgen evidence is so definitely that of a chronic, pre-existing bone lesion in a large majority of such cases. Undoubtedly, a number of these cases of lunatic osteomalacia go through life unrecognized.

REPORT OF CASES

CASE 1—A white man, aged 40, a machine setter, referred by Dr. M. S. Corbett in January, 1928, stated that in November, 1927, without any injury that he could recall, his hand began to hurt a little, and as it gradually got worse he complained of the pain, which interfered with the use of his hand. In December he had gone to a physician, who made a roentgenogram of the hand. He was told that "the x-ray showed a fracture of one of the wrist bones." The patient states that he could remember no injury at all and was puzzled about the occurrence of a fracture without sudden pain. He was treated for a carpal fracture but did not improve. His hand continued to be sore in one spot for several weeks when, becoming discouraged, he applied to Dr. Corbett, Jan. 9, 1928, for attention.

Because of the history of the roentgen finding of a fracture the patient was referred to me for roentgen study of the part. There was some swelling of the soft tissues of the wrist and pain on movement and on pressure over the carpal area. Carpal tuberculosis was considered a possibility. As the result of my roentgen examination I reported the finding of "no evidence of fracture or of tuberculosis but the typical shadows of a case of semilunar osteomalacia." In figure 1, which is a reproduction of the roentgen appearances, Nov. 9, 1929, a year after the onset, the semilunar bone is seen to have lost its normal shape as compared with the opposite one, and the edges of the bone are rough and irregular while its volume has decreased considerably. The cancellous bone detail is lost and the density of the bone is decreased. The patient reports that he cannot use his hand for heavy work nor can he grip handles without more or less pain. He appears to have at least a 50 per cent disability.

CASE 2—A white man aged 42, a laborer, referred to me at the National Pathological Laboratory by Dr. R. W. McNeely, was lifting meat to a truck, Dec. 27, 1929 when he felt something snap in his left wrist. There was no marked amount of pain. Four days later he was first seen by a physician. At that time he had a painful swelling of the left hand and wrist.

A roentgen study revealed on altered lunatic bone but no fracture. This was treated by immobilization. Three months later he returned to work, somewhat improved. At this time the following observations were recorded. He was unable to flex his fingers completely in the palm of his hand, and there was some limitation of flexion, extension and rotation of the wrist. There was slight pain and evident disability.

My roentgenogram, April 22, 1930 (fig. 2), disclosed a pathologic lunatic bone. The shadows indicated an altered outline and certain decreased densities within the deeper cancellous bone. There was no evidence of a fracture line. (I question whether a fracture actually existed at the time of the accident but believe the already softened bone underwent a partial collapse as the result of strain.) The roentgen evidence was clearly that of a malacia of the lunatic bone, as were also the history and subsequent events.

CASE 3—H. M., a man, aged 22, a bricklayer, a patient of Dr. Sumner L. Koch at the Passavant Memorial Hospital, complained of pain and consequent inability to use the right wrist and hand, May 8, 1930. The pain was mainly in the wrist. In March, 1929, the patient noticed that his wrist would pain on twisting and on lifting objects. At that time the pain was

Fig. 2—Appearance of left wrist showing softened bone area in deep cancellous structure. The usual sequence to this state is the shrinkage incident to the softening of the bone tissues.

not definitely localized, nor was it very marked. In April he consulted a physician, who diagnosed it as a wrist sprain and gave him a light treatment but there was no relief from symptoms. He then went to another physician who also considered it a sprain and prescribed an analgesic sale and rest for ten days. However, he played ball every evening during this time. He noticed some relief during rest but pain recurred on resuming work. He then consulted the company's physician, who suggested a wrist strap and rubbing lotion. The patient had roentgenograms taken at this time but did not wear the strap. He did not learn what the roentgenograms showed. In July the pain became worse, so the physician suggested seeing a specialist in Minneapolis. In August the patient quit work because of the pain and went to see the physician in Minneapolis who took roentgenograms and applied a cast, which was kept on for two months. Following this a brace was put on and kept on until January, 1930. The pain was relieved by this immobilization. In January the patient began a business course but typewriting hurt his wrist so he gave this up. He was advised to rest indefinitely and not to use his hand much. This has not given him relief. His wrist has become rather stiff. A roentgen study by Dr. J. T. Case discloses a definite pathologic process confined to the lunatic bone and was diagnosed as

Kienbock's disease. Operative removal of a softened and necrotic lunate bone was performed by Dr Koch, the crumbled bone tissue offering considerable difficulty when complete removal of the diseased bone was attempted.

CASE 4—W. P. M., a white man, aged about 30, was referred by Dr. Michael Mason to the x-ray department of Wesley Memorial Hospital, Feb. 18, 1928. He came to the hospital with an acute condition of the hand following an injury. He was an outpatient and therefore the records are not complete. Roentgen study at this time disclosed a lesion of the lunate bone, the

Fig. 3—Appearance of right carpal bones in case 3 as found by Dr. Case about two years after onset. Presents the typical shrinkage of Kienbock's disease.

features of which indicated an old and not a recent change. This might, however, have been an aggravation of an old process in which fracture may have been a part. An analysis of the roentgen shadows disclosed a decrease in the volume, and irregular decreases in density had features of necrosis and disintegration, typical of an osteomalacia of the semilunar bone.

SUMMARY

1. Lunate osteomalacia occurs more frequently than is recognized.
2. Most often it is diagnosed as a fracture, even in cases in which there is no history of an accident or direct injury.
3. Twisting, or a blow to the wrist, is a frequent occurrence that results in the roentgen disclosure of a preexisting pathologic condition of the lunate bone.
4. The essential change is that of a softening of the bone with necrosis and deformity.
5. The surgical removal of the diseased bone does not materially reduce the disability.
6. This lesion often results in a major degree of disability.

727 West Seventh Street

ABSTRACT OF DISCUSSION

DR. HOWARD P. DOUB, Detroit. The clinical observations have been well covered by Dr. Blaine. The thing that is most interesting to me is the question of etiology. This condition in some ways simulates Kohler's disease and some of the familiar conditions of epiphysitis. However, it most nearly simulates Kummell's disease. The etiology of these conditions has not been settled. There are some significant facts, however,

that might be mentioned. Hulten states that he has studied the anatomic anomalies in 400 cases of normal wrist joints and in these he finds 23 per cent in which the ulna is shorter than the radius. He finds other variations. I will dwell only on this. He finds that Kienbock's disease is particularly prone to occur when the ulna is shorter than the radius but never when the radius is shorter than the ulna. Preiser and Kienbock believe that no primary fracture occurs. However, some authors have claimed that, if films were made in various oblique positions, a fracture could be found in these cases. On studying the history of some of the cases reported and from the history of Dr. Blaine's cases this would not seem to be supported, because many of these patients had had their wrists subjected to chronic minor traumas only, such as laying bricks and things of that type. Kienbock believes that it is often caused by a partial or complete subluxation of the bone with spontaneous replacement, in that way destroying the blood vessels and leading to faulty blood vessel supply. However, Buchman has removed a number of these bones and has examined them microscopically, and he reports that he has found the bone tissue and marrow replaced by fibrous tissue. He also finds an increased blood supply rather than a decreased blood supply, and because of that he says that Leriche's theory that there must be increased blood supply in order to produce osteomalacia would seem to be supported. Another thing every physician has noticed at one time or another is the fact that a dead piece of bone is always more dense than a normal piece of bone, and that possibly might lend some support to this theory. The etiology, however, after all is said and done is uncertain, but these facts are interesting in the study of this condition.

DR. THEODORE SOKOW, Kenosha, Wis. I really believe this disease is not as rare as is commonly thought. There are many people treated for rheumatic conditions or for sprains who really have this condition, only it is not recognized. One who

Fig. 4—Appearance of lunate bone in case 3 showing some disintegration, malformation and some shrinkage.

reads ten or fifteen papers written about this subject will find ten or fifteen different opinions about the etiology of this disease. I think Dr. Blaine's explanation is the right one. It must be figured that this condition is found in men and women between the ages of 20 and 40, mostly in men, always in hard working people who are exposed to different injuries. I believe that this disturbance of the semilunar bone is produced by trophic disturbances. Dr. Blaine mentioned a disease of the carpal bones which is not explained so far, some kind of degeneration, formation of small fine cysts, which a good observer can see in many cases, often overlooked. I believe, as Dr. Blaine explained, that

this so called osteoporosis has some relationship to Kienbock's disease. The opinions about treatment of this disease vary. Some authors recommend surgical and others, conservative, medical treatment. The results are good and bad in both kinds of treatment. I observed the case of a man of about 35. He refused surgical treatment, so I started medical treatment with immobilization and physical therapy. I happened to see the man exactly three years later. His hand showed a slight swelling, but there was no pain, the function was only slightly impaired and he was able to do his former work. I think that too much haste should not be shown in recommending surgical treatment. Sometimes, conservative treatment may work out all right.

INCOMPLETE DILATATION OF THE LUNGS AS A FACTOR IN NEONATAL MORTALITY*

YANDELL HENDERSON, PH.D.
NEW HAVEN, CONN.

Many children now die at birth or within the neonatal period who could and should live. Among these fatalities the largest group is that which results from one or other of such related conditions as primary or secondary failure of respiration, inadequate expansion of the lungs, and pneumonia developing from atelectasis.

The knowledge requisite to save a large percentage of these lives is now available. It is clear and certain. The method of its application is simple and inexpensive. It is merely an inhalation of carbon dioxide in oxygen for a few minutes several times a day during each of the first few days of life. Every new-born child, even those that appear normal, should receive this treatment as a prophylactic to insure early and complete relief of atelectasis. The hazard of neonatal pneumonia is thus largely eliminated. For the prevention of blindness, disinfection of the eyes with silver nitrate is, in most states, required by law. The inhalation of the mixture of carbon dioxide and oxygen requisite to insure full expansion of the lungs would save many times more lives than this treatment of the eyes prevents cases of blindness. In order to be universal, it will need to be legally required.

For 1927 the Bureau of the Census¹ reported for the birth registration area, or 87.3 per cent of the population, 82,931 stillbirths and 2,137,836 live births—a relation of nearly 4 to 100. Of those infants listed as live births 32,180 died within a day, 8,848 the next day, 6,345 the third day, 11,351 in the next four days, 8,296 in the second week, 5,457 in the third, and 4,617 in the fourth, a total of 77,094 in the first month, and 138,017 in the first year. Together, the stillbirths and neonatal deaths amount to nearly 8 per hundred births. If the statistics for stillbirths were more accurate, the figure would probably be 9, or possibly even 10, per hundred, a tremendous mortality. Premature birth is given as the largest single cause of death, 35,916, but prematurity cannot logically be accepted as in itself a cause, for unless a premature child fails in some func-

tion it lives. It is safe to assume that especially in the premature the real, but unrecognized, cause of death is often incomplete relief of atelectasis, secondary failure of respiration, and pneumonia.

UNRELIEVED ATELECTASIS

These statements in regard to atelectasis and pneumonia are largely based on the recent study by Cruickshank² of the causes of neonatal death as shown by 800 autopsies. That report states:

The importance of asphyxia neonatorum as a cause of neonatal death is emphasized by the fact that almost 68 per cent of the 800 infants included in the present series died from this cause alone. Many of the cases which have been placed in the group of deaths from infection were doubtless predisposed to these infections by the effects of birth asphyxia. It is obvious that a deeply congested and imperfectly expanded lung is much more liable to the development of pneumonia than one in which circulation and aeration are free (page 22). There were 197 cases of pneumonia in the whole series of 800 neonatal deaths, so that this is the most common of all the infective lesions found. It was present in practically a quarter of the infants in the present series, and if deaths from asphyxia, prematurity and atelectasis are excluded, the frequency of pneumonia was practically 2 in 3. Of the infants which died during the first week of life 60 had pneumonia, during the second week there were 87, during the third week 37, and during the fourth week 13 (page 29).

Cruickshank defines the neonatal period as the first month of life.

These observations suggest, and others quoted later verify the suggestion, that even in apparently normal babies complete dilatation of the lungs may not be attained for hours or even days. Considerable areas of atelectasis escape detection by any means but the x-rays. For this reason it is not surprising that Cruickshank should have found nearly 25 per cent of cases of pneumonia in his whole series of neonatal deaths. This percentage is indeed much higher than any other observer has reported. It is accounted for by the fact that the diagnoses were based on histologic examination. Cruickshank's results indicate, therefore, that unrecognized pneumonia consequent on continuing areas of atelectasis is a far more frequent cause of death during the neonatal period than has been heretofore realized. It is particularly to remove this unrecognized hazard that inhalation should be legally required.

Wasson,³ in this country, has reported a roentgenographic study on the lungs of new-born children, showing that even in normal cases full expansion of the lungs does not always occur immediately after birth. "In some cases of normal, easy delivery with the child in good condition, the lungs gave the appearance of full expansion within five minutes after delivery. Again in similar cases of easy delivery, but especially in those of prolonged difficult delivery, the expansion of the lung was found to take place slowly, leaving entire lobes atelectatic or with only scattered areas of atelectasis."

We called the lung fully expanded when there was air throughout all the parenchyma and no evidence of scattered density suggesting remaining atelectasis. The interval of time for this to take place ranged from five minutes to two weeks. The observation that atelectasis continues in some cases for as long as two weeks is highly significant.

Von Reuss⁴ summarizes the evidence of German observers on this subject thus

The lung does not undergo complete expansion at the first breath. The researches of Dohrn and Recklinghausen show that the respiratory exchange is extremely small on the first day. Measurements of the lung capacity yielded twenty minutes after birth 17 cc, three and a half hours after birth 21 cc, six hours after birth 36 cc. The depth of inspiration acquires a considerable increase between the first and second day, but many days pass before complete expansion of the lungs occurs. Peiser attributes this circumstance to the incomplete development of the nervous system, to the relatively slight reaction of the respiratory center to the irritation of CO₂, and to the fact that infants move very little and therefore the muscular system only produces in very small amount those irritant substances which stimulate the respiratory center. The expansion of the lung is longer delayed in debilitated and premature infants. Pneumonia, which is very apt to supervene when the risk of infection exists in the atelectatic portions of the lung, is a very frequent cause of death in premature infants. The treatment of atelectasis must be directed toward expanding the lungs by stimulating deep respirations.

To this end cutaneous stimulation to cause the infant to cry is recommended in mild cases, while for the still-born all methods of stimulation and artificial respiration should be applied, although all are often ineffective. Von Reuss quotes statistics (p. 290) which indicate, contrary to a common belief, that mental defects are no more frequent in children who have undergone difficult and asphyxial birth than in those of quite normal birth. Among those resuscitated from stillbirth he says that from 20 to 30 per cent succumb to sequelae, especially in the first two days, while through the first week the mortality among such infants is seven times the rate of those born normally. In the majority of cases (p. 289) this "is due to atelectasis from insufficient expansion of the lungs" or to obstruction, added to which is "the danger of inflammatory lung complication in atelectatic parts of the lung."

The account which von Reuss gives of asphyxia and continued atelectasis, their causes and consequences is an admirable presentation of present knowledge and practice. The only thing lacking is an effective means of combating these conditions and saving life.

PNEUMONIA FROM ATELECTASIS

Recent developments along several distinct, but parallel, lines lend further strong support to the conception of the association of atelectasis and pneumonia. Coryllos and Birnbaum⁵ have presented experimental evidence, which I can confirm from personal observation,⁶ that even in an animal so resistant to pneumonia as the dog atelectasis furnishes a condition in which pulmonary infection readily develops. That pneumonia may originate in atelectasis, when induced in an adult, as these investigators have demonstrated, is a discovery of extreme importance. On the clinical side, recent evidence⁷ from many surgeons and anesthetists demon-

strates that atelectasis frequently occurs after abdominal operations and is the origin from which postoperative pneumonia develops. By the prevention of postoperative atelectasis in clinics where the prophylactic inhalation of carbon dioxide after every operation has been adopted as a routine, postoperative pneumonia has been virtually relegated to the class of preventable and prevented diseases.

Equally important collateral evidence is afforded by experience resulting from the study of carbon monoxide asphyxia.⁸ Formerly pneumonia was a common and often fatal consequence of this form of asphyxia. The relation was long obscure, but it has become clear from the results of the modern inhalational treatment with a mixture of oxygen and carbon dioxide, for in cases so treated postasphyxial pneumonia almost never occurs. The oxygen overcomes asphyxia, but it is the carbon dioxide that induces deep breathing and thus eliminates the condition of the lungs from which pneumonia otherwise often develops.

A closely similar etiology is thus indicated in three conditions that have heretofore been regarded as quite unconnected: (1) anesthesia and postoperative pneumonia, (2) carbon monoxide asphyxia and postasphyxial pneumonia, and (3) asphyxia of the new-born, atelectasis and pneumonia. That fundamentally these three syndromes are essentially alike is demonstrated by the fact that the same prophylactic inhalational treatment is effective in clearing the lungs and preventing fatalities in all three.

Observations, now in progress, on the use of a similar inhalational treatment early in both lobar and bronchopneumonia in adults indicate that in these conditions also it is advantageous, not only to prevent cyanosis by means of oxygen but also to keep the lungs open by stimulating deeper breathing by means of carbon dioxide. The inhalation has been generally administered intermittently by means of the face mask of the H-H inhalator, but a small tent has now been specially designed for continuous inhalation. These observations are under the direction of Dr. J. J. Wittmer, supervising physician of the New York and Brooklyn Edison Companies, the Brooklyn company having made this treatment available not only to its own employees but also during the past year for other pneumonia cases in Brooklyn. The mortality among cases treated early with a mask before the tent was available has been 11 per cent.

In these four related conditions, that of carbon monoxide asphyxia is of especial interest in the present connection. There are now all told in American cities and industries several thousand rescue crews each equipped with an inhalator and trained to resuscitate the victims of carbon monoxide asphyxia by inhalation of oxygen and carbon dioxide. I receive reports of many of the cases so treated. There are frequent reports also of the resuscitation of the new-born, cases both of asphyxia livida and asphyxia pallida, and of the treatment of secondary failure of respiration, continuing atelectasis, and neonatal pneumonia. It was, in fact, by these reports that the discovery of the true nature of the asphyxia of the new-born forced itself on me. They show that the inhalational treatment is frequently successful in cases in which every other means has failed. They afford a clear demonstration

that this method of resuscitation is quite as effective and as specific for the asphyxia of the new-born as for asphyxia from carbon monoxide

CARBON DIOXIDE AS THE STIMULUS FOR THE FIRST BREATH

This discovery is so completely in accord with present physiologic theory that it may now seem that it should have been anticipated from two classic papers that of Miescher⁹ published forty-five years ago, and that of Haldane and Priestley¹⁰ published twenty-five years ago. Yet, when one reads Miescher's celebrated presentation of the overwhelmingly complex and difficult problem of the control of respiration, a problem still largely unsolved,¹¹ one ceases to wonder that through all these years no one demonstrated the truth of this inference from the theory of respiration. Instead, the nonbreathing new-born child down to the present day has been swung, chilled and spanked.

Our failure to see the simple truth as it applies to the first breath of life was really quite logical. There was an unanswerable argument against application to the new-born of the Miescher-Haldane theory of the chemical control of respiration. It was to the effect that an asphyxiated child certainly has in its blood a normal or even more than normal pressure of carbon dioxide, yet it does not breathe. If the sensitivity of the respiratory center is decreased, or even abolished, by accumulation of carbon dioxide in birth asphyxia, how then can it be carbon dioxide that normally sets respiration in operation at birth? The initiation of respiration under the chemical stimulation supplied by the blood appeared altogether improbable. No experimenter, obstetrician or pediatrician less bold than the rescue crews of the Chicago Fire Department, who, untroubled by theory, first demonstrated this point and called it to my attention, would have dared to administer carbon dioxide to an asphyxiated new-born child.

Furthermore, it was known that a moderate deficiency of oxygen such as occurs at altitudes in the Rocky Mountains, Alps, Andes and Himalayas does not depress the sensitivity of the respiratory center. On the contrary, as found by the Pike's Peak Expedition,¹² and confirmed by many other observers since, the sensitivity of the respiratory center is much more acute under a low barometric pressure than at sea level. Respiration is greatly increased, the alveolar carbon dioxide pressure is lowered, and the time that the breath can be held voluntarily is considerably shortened. Similarly in carbon monoxide asphyxia the subject breathes excessively and blows off his own carbon dioxide to such an extent that acapnia is added to anoxemia.

There are many drugs and other influences which first stimulate a living organism and then depress its functions. But there was nothing in the effects of low oxygen on mountains or in mines, nor in those of carbon monoxide poisoning, to suggest that asphyxia

may decrease the sensitivity¹³ of the respiratory center to carbon dioxide. No one had observed or suggested that an asphyxiated respiratory center requires a higher pressure of carbon dioxide than normal to induce and maintain its activity.

It has long been known that respiration may be depressed by excess of carbon dioxide. Some of the earliest investigators failed to discover that carbon dioxide is a respiratory stimulant, because they used excessive amounts in their experiments and obtained only depression. All modern observers seem to agree that, up to about 10 per cent, increasing amounts of carbon dioxide in the inhaled air stimulate the respiration of a normal man or animal increasingly, but that above 10 per cent a depressant effect is induced, which with percentages around 15 or 20 passes into narcosis, and at 30 or higher may cause death. But it is really surprising that, as we now find, a center which has been depressed in this way is susceptible of being stimulated to virtually normal activity by inhalation of carbon dioxide.

Some evidence on this subject is afforded by experiments of Henderson and Haggard,¹⁴ who found that when dogs were subjected for a considerable time to atmospheres containing a normal amount of oxygen, with a high partial pressure of carbon dioxide, not only was there an accumulation of carbon dioxide in the blood but the blood alkali also rose. This compensatory increase of the blood alkali necessarily tended gradually to decrease the sensitivity of respiration to carbon dioxide. In one animal that was kept breathing normal air plus amounts of carbon dioxide increasing gradually from 6 up to 20 per cent during five hours, the carbon dioxide capacity, or alkali reserve, rose from 50 to 74. "When the animal was finally allowed to breathe normal air again its respiration ceased after a few breaths and a fatal apnea followed. Apparently the alkali content of the blood had been raised so high that when the abnormally high pressure of carbon dioxide was withdrawn the respiratory center lacked an adequate stimulus."

Whether or not something of this sort occurs in men and animals who are drowned and in infants during prolonged birth is not known. It seems probable that, in such short exposures to excess of carbon dioxide as occur in drowning, the depression of sensitivity must be in the center itself rather than in any increase of blood alkali.

DEPRESSION OF THE RESPIRATORY CENTER BY ASPHYXIA

It is not the logic, but the evidence, that has been deficient and misleading. Success in resuscitation of the new-born by the inhalational method has now demonstrated that, contrary to current assumption, a partially asphyxiated respiratory center will respond to stimulation by carbon dioxide. But after asphyxia more than a normal pressure of carbon dioxide is required to induce the center to become active. Its sensitivity to chemical stimulation is greatly altered in degree but not in character.

In the normal child the respiratory center is sufficiently sensitive, so that breathing is induced under the

stimulus merely of the carbon dioxide supplied by the child's own respiratory metabolism. Observations on nonbreathing infants show that under prolonged asphyxia the respiratory center undergoes a loss of sensitivity analogous to that known to be induced by morphine. The center then requires a stronger chemical stimulus than the body can supply. It responds in quite normal fashion, not to the normal pressure of 5.5 per cent of carbon dioxide but only to 7, 10, 15 or 20 per cent of carbon dioxide, according to the degree to which its sensitivity has been reduced by asphyxia.

Until this point was covered by decisive evidence it could not logically be asserted, as it can now, that in the normal child breathing is induced under the stimulus of its own carbon dioxide and that a partially asphyxiated new-born child is not stimulated to breathe when it is swung or chilled or sprinkled, but only when the chemical stimulus to its respiratory center becomes sufficiently strong to induce activity.

EVIDENCE FROM DROWNING AND INTRACRANIAL HEMORRHAGE

Support for this conception is afforded by the reports of bathing and boating accidents which I have collected and which show that a similar depression of the respiratory center occurs in the victims of drowning. Although the body of a drowned person doubtless contains more than a normal amount of carbon dioxide, it is insufficient to overcome the depression and to stimulate the center again to spontaneous activity. But the center is not paralyzed, given a renewed supply of oxygen, it responds to the chemical stimulus of carbon dioxide, for the reports of many resuscitations that have come to me show that the administration of carbon dioxide in oxygen is a powerful aid to artificial respiration in restoring natural breathing.

A similar depression of breathing sometimes occurs also during a slow intracranial hemorrhage after an operation on the brain. It was shown by White¹⁵ that this depression of breathing could be combated and life saved by stimulating respiration by inhalation of carbon dioxide diluted in air. This fact is particularly significant in the present connection, for secondary failure of respiration in the new-born is frequently due to intracranial hemorrhage. Sword¹⁶ has found that, in those infants in which secondary failure of respiration is probably due to intracranial hemorrhage, inhalational treatment is often effective.

INHALATIONAL RESUSCITATION OF THE NEW-BORN

A previous paper¹⁷ in *THE JOURNAL* presented the evidence then available on resuscitation of the new-born. It came largely from the rescue crews of city fire departments and need not be here repeated. But the evidence that has accumulated in the three years since may be briefly summarized. For it I am indebted to a number of obstetricians who have now given up the ancient methods of treating neonatal asphyxia and have adopted the inhalation method. Their statements are unanimous to the effect that, in cases similar to those in which formerly breathing was started only after an anxious struggle and considerable manhandling of the child, respiration starts readily once the lungs

are moderately dilated with a mixture of oxygen and carbon dioxide. In every hospital, so far as I can learn, in which the inhalational method of resuscitation has been tried it has now replaced the older procedure and has resulted in a distinct decrease of mortality. Furthermore, it is found that secondary failure of breathing some hours or days after birth, a condition before which the physician was formerly practically helpless, is now easily and effectively overcome. In the pediatric department of one large hospital, which has kindly given me a report, such cases as those which Cruikshank described have been extremely rare since the inhalation method was introduced.

TYPES OF INHALATOR

For use in resuscitation alike of adults and of infants in all forms of asphyxia, the so-called physicians' type of the H-H inhalator¹⁸ is the most generally serviceable portable apparatus. It was with this apparatus that most of the evidence recorded in this paper has been obtained.

For use only on infants, a simple inhalator was figured in a previous paper.¹⁷ A convenient portable inhalator for infants is that of Foregger.¹⁹ It consists of a cylinder of oxygen and carbon dioxide, a yoke having a finely adjustable regulating needle valve, a wash bottle, and a soft rubber bag connected to a light mask of metal or celluloid. It is best to use a mask large enough to enclose the entire face of the infant, not merely the nose and mouth, fitted with an inflatable rubber rim so that it can be held on the face as nearly air-tight as possible. All that is absolutely essential is a mask and rubber bag, such as those just described, with shut-off, or obturator, valves at each end of the bag. The bag is filled as needed from a cylinder of the gas mixture.

For premature infants especially it is often best to use a small chamber, a box herited from below, and with a glass top. A convenient apparatus of this type has been introduced in England by Mellroy.²⁰

Expert anesthetists, who use their anesthesia apparatus also for resuscitation, find the most convenient mixture of gases for use in a wide variety of conditions—anesthesia, carbon monoxide poisoning, cerebral hemorrhage, birth asphyxia, morphine poisoning, persistent hiccup—to be 25 per cent carbon dioxide and 75 per cent oxygen. This mixture is not used in full strength in any but desperate cases, it is usually diluted to any desired degree with pure oxygen from another cylinder. The use of high percentages of carbon dioxide, that is, above 10 per cent, is probably unwise except for those with skill and experience, yet they permit a saving of a few lives that cannot be effected with lower percentages, for the deeper the asphyxial depression, the higher the percentage of carbon dioxide required to induce breathing. Lower percentages, of which 7 per cent is generally best, are wholly safe even in inexperienced hands, and in the large majority of cases afford a quite adequate stimulation.

USE OF AN INHALATOR ON THE NEW-BORN

If the child makes no spontaneous respiratory effort, artificial respiration is applied as follows. The rubber bag of the inhalator is filled with gas from the cylinder,

which may then be shut off. The mask is held as nearly as possible air-tight on the face, while the bag is compressed quickly but gently with the hand for half a second or one second, so that the thorax of the child shows a slight expansion. This gentle compression of the bag is repeated every two or three seconds, so that the expansion of the chest is effected in a succession of small steps. If, after the thorax is thus somewhat inflated, no expiratory movement occurs, a gentle pressure is applied with the hand on the sides of the child's chest to produce expiration. The pressures on the bag are then renewed for three or four gentle inspirations, and followed by a gentle compression of the chest by hand, and this process is repeated from four to six times a minute.

Generally, under this treatment, natural breathing soon develops. The mask is then held continuously on the face for ten minutes or until full deep breathing is established. Rebreathing is no disadvantage, for the amounts of oxygen that an infant consumes and of carbon dioxide that it produces are small in comparison to the size of the breathing bag of the inhalator.

Every child, even the most normal, should have a ten minute inhalation at least three times a day during the first few days of life as a prophylactic measure against atelectasis and pneumonia. In a child that receives this inhalation the various devices heretofore used to make the child expand its lungs by crying, such as stinging the soles of its feet with a rubber elastic band and the like measures, may be omitted.

THE USE OF A RESPIRATOR

The question is often raised whether some mechanical or automatic device for artificial respiration is desirable for treatment of the new-born. The answer is an emphatic negative. If an asphyxiated child can be resuscitated at all, it requires only a short period of artificial respiration but without the delay involved in adjusting an elaborate device. A simple mask with a breathing bag that can be compressed by hand to afford inspiration and manual pressure on the chest for expiration are quite as effective as any more complicated apparatus can ever be, and without the risk of injury to the lungs which such apparatus involves. The purpose of artificial respiration for the new-born should be to draw into the lungs a mixture of oxygen and carbon dioxide sufficient to relieve asphyxia, to set natural breathing in operation, to induce the child to dilate its lungs and overcome atelectasis. In other words, the object is to get the child to breathe vigorously for itself.

These statements refer particularly to such apparatus as the pulmotor and lungmotor. The Drinker respirator,²¹ recently introduced, belongs to a different class of apparatus and has an important place. It is primarily designed to maintain long continued artificial respiration in cases of diphtheritic paralysis and poliomyelitis. For this purpose it is extremely useful and indeed lifesaving.

INTRODUCTION OF INHALATIONAL TREATMENT

The new knowledge reviewed here regarding the initiation of respiration and the risks of unrelieved atelectasis will be of little value unless put to use. Unfortunately, inhalational treatment does not introduce itself like arsenamine or insulin. Experience shows that many physicians will not provide themselves beforehand with the necessary apparatus and that even hos-

pital superintendents are reluctant. In order to attain maximal effectiveness, inhalational treatment of the new-born will need to be required by law.

As a preliminary to legal enforcement, it is essential that some agency in each city should provide itself with infant inhalators and supply them to physicians and midwives at a rental for each case sufficient merely to cover the cost of the small amount of the gas used. The city health department is obviously the proper agency to supply the inhalators, to give the necessary simple instructions to midwives, and to maintain some degree of supervision over the respiratory prophylaxis of the new-born outside of hospitals.

CONCLUSIONS

The natural stimulus initiating breathing in the normal child at birth can now for the first time be stated on sufficient evidence to be the carbon dioxide produced in its own body. While physiologic theory for many years past has suggested this view, the objection could not be overcome that a nonbreathing child probably has a higher pressure of carbon dioxide in its blood than one that breathes spontaneously. The evidence from the effects of inhalation, as set forth in this paper, clears away this objection. It shows that the asphyxiated respiratory center of the new-born, or of a drowned person, requires a much higher pressure of carbon dioxide than does a normal center to stimulate it to respiratory activity.

This conclusion, which now seems so simple, is in reality the result of a long succession of arduous, abstract and theoretical studies on the meaning and control of respiration by many investigators, not only in modern times but during generations and centuries past.²²

For the asphyxiated new-born child, dilation of the lungs with a mixture containing a sufficient amount of carbon dioxide in oxygen to stimulate natural breathing is the one really effective method of resuscitation.

Inhalation of this mixture²³ is equally important for many children that breathe spontaneously, for among these cases incomplete dilatation of the lung is a common condition, predisposing to pneumonia and causing nearly as large a mortality as stillbirth itself. This inhalation should therefore be administered not only to those infants who require it for resuscitation from asphyxia but to all children, even to those that appear entirely normal, during the first few days of life as a prophylaxis against continuing partial atelectasis, secondary asphyxia, and pneumonia.

Every maternity hospital should be equipped with at least a simple inhalator for the new-born, or better with an inhalator suitable for infants and adults as well, so that the mother may also be treated when an anesthetic or narcotic has been used. For deliveries outside of hospitals the city health departments should provide simple infant inhalators to be rented to obstetricians and midwives for the cost merely of the oxygen and carbon dioxide consumed. After a reasonable period of education for obstetricians, midwives and nurses, a legal requirement similar to that for the prophylaxis of blindness should be established. Only under such requirement will the inhalational prophylaxis of atelectasis come into such general use that it may save the greatest possible number of lives.

²³ In practice this mixture is called carbogen. 7 per cent carbogen is 7 per cent carbon dioxide and 93 per cent oxygen.

THE FEEDING OF GASTRIC TISSUE
IN THE TREATMENT OF PER-
NICIOUS ANEMIA*II MILTON CONNER, MD
ROCHESTER, MINN.

Castle and Locke¹ fed muscle meat to normal persons, recovered the meat by causing vomiting, and refed it to patients who had pernicious anemia thus causing a response of reticulated erythrocytes, an increase in the number of erythrocytes, and clinical improvement similar to that found when liver or its extract was used.

This work led Sturgis and Isaacs,² in collaboration with Sharp,³ to try the effect of feeding desiccated gastric tissue to patients who had pernicious anemia, with results similar to those obtained with liver or its extract. Likewise, Castle and Locke's work led me to feed raw gastric tissue to patients who had the disease, with results which already have been reported in six cases,⁴ and which were similar to those obtained with liver and liver extract. Another fact which suggested the use of gastric tissue was that I⁵ had found that in approximately 26 per cent of 154 relatives of more than 100 patients who had pernicious anemia, the gastric content lacked free hydrochloric acid. Eighty per cent of these tests were made by the fractional method. This fact, and the achylia found in practically every case of pernicious anemia served to fix attention on the stomach as a possible etiologic factor and made the feeding of gastric tissue seem a logical procedure. Wilkinson,⁶ also, was influenced by Castle and Locke's work to carry out similar experiments in cases of pernicious anemia. He fed both raw and desiccated gastric substance, with similar results. Snapper and Dupree,⁷ Renshaw⁸ and Rosenow,⁹ following these original workers, have reported similar results of feeding the same material.

I have prescribed treatment with gastric tissue of swine in some form, or with honeycomb tripe (pickled gastric tissue of cattle), for sixty patients. Certain of these were excluded from this study. For example, four patients whose treatment consisted mainly of tripe were not included. Two were not considered in this paper because the treatment with gastric tissue of swine was discontinued in a few days, in one case because of poor cooperation on the part of the patient and in the other because the patient's relatives wished to take him home on account of marked neurologic symptoms, for relief of which I could promise nothing.

Two of the remaining fifty-four patients were fed swine stomach after failure of treatment with tripe, and five were sent home for treatment without having been treated at the clinic. One has been under treatment only a few days at the diet kitchen. The remaining forty-six patients were under careful observation in the hospital and are included in the detailed study.

Sixteen of these forty-six patients were fed raw whole stomach of swine exclusively, six raw mucous membrane of the entire stomach with other meat, two the same without other meat, two, raw whole pyloric portion, two raw whole fundus, and one patient raw entire gastric wall save mucosa without other meat. Three patients were given whole stomach dried in our own laboratory, and six a preparation of desiccated hog stomach according to the method described by Sharp and by Sturgis and Isaacs. Eight patients were given various combinations of these, including, also, mucous membrane dried by one of the packers. These combinations were made because of temporary exhaustion of the supply of one or another substance, because of greater ease in taking one than another, or because of the difference in expense. The results of the use of all these different preparations are considered as a unit, as the results were so similar. The results with tripe are not included in this report, for they were inconsistent and unconvincing. It can be said, however, that the effects of tripe were much inferior to those with raw or dried gastric tissue of swine. When entire gastric wall was used, from 240 to 480 Gm daily was given, whereas half this amount was given when mucous membrane alone was used. A corresponding amount of the dried material was used, making allowance for shrinkage to a sixth or a seventh of the original weight in the process of desiccation. The raw material, after it was ground in a seprasiave usually was given in orange, tomato, cranberry or other fruit juice, and the dried material was given in fruit juice or water, as preferred. The taste or smell of the raw stomach was not objectionable to most patients.

In most instances a regular hospital diet was administered also, but in a few cases other meat of any kind was not allowed. Significant difference was not noted as a result of eliminating other meat. In one case, in which that part of the gastric wall employed consisted of 240 Gm of mucosa only, without other meat, but with 100 Gm of other proteins, mostly of animal origin, the proportion of reticulated erythrocytes increased from 0.8 per cent to 33.4 per cent in eight days, and in another, similarly treated, they increased from 0 per cent to 10.6 per cent in six days. In one case in which entire gastric wall except mucosa was given, the proportion of reticulated erythrocytes increased from 0 per cent to 33.8 per cent in seven days. In this case, other meat was not given. It is possible that the mucosa, before it was removed, may have exerted some action on the muscular coat which made it effective, but it seems unlikely that the minute amount of muscle in the muscularis mucosae could produce any large part of the effect in those who were fed mucosa only without other meat. In two cases, the remainder of the diet was selected for its high content of vitamins but did not include liver. In only two cases was hydrochloric acid used. A further trial of hydrochloric acid in conjunction with the feeding of gastric tissue will be made.

Cooked gastric tissue was used in only one case because Castle had shown that the substance which

caused the favorable reaction was thermolabile¹⁰ Before any effect was obtained, because of marked vomiting, administration of cooked gastric tissue was discontinued and desiccated hog stomach was administered instead. This case was not included in the table of results. Only one patient was given transfusions, two in number. This patient probably made the poorest response in the whole group. The results of the use of desiccated hog stomach were so unsatisfactory in this case that liver extract was substituted, after which there was better response.

The effects on the blood are best considered by dividing the cases into groups according to the number of erythrocytes in each cubic millimeter of blood when the treatment was instituted, as follows: group 1, less than 1,000,000; group 2, between 1,000,000 and 2,000,000; group 3, between 2,000,000 and 3,000,000; and group 4, between 3,000,000 and 4,000,000.

The percentage of reticulated erythrocytes among all erythrocytes, which is almost universally accepted as the criterion by which regeneration of blood is judged, increased most markedly in the cases in which the treatment was started when the number of erythrocytes was small. In cases in which the erythrocytes numbered more than 2,000,000 in each cubic millimeter of blood, the increase in the percentage of reticulated erythrocytes was not so great, and in those in which erythrocytes numbered more than 3,000,000, only moderate or slight increase in the percentage of reticulated erythrocytes was seen. In the whole group, the proportion of reticulated erythrocytes rose to a maximum of 65.8 per cent in one case, to 40 per cent in one, to between 30 and 40 per cent in six cases, to between 20 and 30 per cent in five, and to between 10 and 20 per cent in thirteen. The proportion of reticulated erythrocytes of 65.8 per cent is the highest I have ever observed in a case of pernicious anemia under any form of treatment. The patient in this case received half a pound daily of the entire thickness of the wall of the pyloric portion of the stomach only. In the group of patients whose treatment was started when the erythrocytes numbered less than 1,000,000, the proportion of reticulated erythrocytes increased to an average maximum of 24.3 per cent¹¹ in eight and three-fourths days, the number of erythrocytes from 910,000 to 2,040,000 and the concentration of hemoglobin from an average of 18.8 per cent to 44 per cent in nineteen days. In those whose treatment was started when the erythrocytes numbered between 1,000,000 and 2,000,000 the proportion of reticulated erythrocytes increased to an average maximum of 22.8 per cent in nine and a half days, the number of erythrocytes from 1,510,000 to 2,800,000 and the concentration of hemoglobin from 32.8 to 56.5 per cent in an average of twenty-one and one-fourth days.

In the group of patients whose treatment was begun when the erythrocytes numbered between 2,000,000 and 3,000,000 the proportion of reticulated erythrocytes increased to an average maximum of 6.9 per cent in approximately eight days, the number of erythrocytes from 2,350,000 to 3,510,000 and the concentration of hemoglobin from 52 to 71 per cent in an average of nearly twenty-five days. In those whose treatment was started when the erythrocytes were between 3,000,000 and 4,000,000 the proportion of reticulated erythrocytes increased to an average maximum of 3.6 per

cent in seven days, the number of erythrocytes from 3,360,000 to 3,710,000, and the concentration of hemoglobin from 70 to 76 per cent in an average of nineteen and a half days. The two instances in which the proportion of hemoglobin was estimated before treatment as grams in each 100 cc of blood were left out of consideration in figuring the average. Most of those patients who had a high proportion of hemoglobin and a large number of erythrocytes when treatment was started had marked neurologic symptoms. In many cases the number of erythrocytes decreased for a few days after treatment was started before sufficient time had elapsed to obtain any effect. If the increase should be figured from the lowest level obtained after treatment was instituted, the figures for the average increase in the number of erythrocytes in the several groups would be from 13 to 26 per cent higher. At the last report, either by letter or by examination at The Mayo Clinic, the highest number of erythrocytes in any case of the whole group was 6,000,000, the lowest 2,800,000, and the average 4,394,000, the highest percentage of hemoglobin was 100, the lowest 65, and the average 80.86. In several instances the increase in the proportion of reticulated erythrocytes was delayed much beyond the average, and in several it was prolonged over several days instead of reaching a sharp peak from which it fell rapidly. The number of leukocytes in the whole group increased from an average of 4,873 to one of 6,464 and the platelets from 101,540 to 118,000.

In the blood smears, after treatment, diminution or disappearance of the microcytosis and anisocytosis was seen, and also disappearance of nucleated erythrocytes in cases in which they had been present. In some instances the distribution and character of leukocytes returned to normal, but in others the shift to the right remained as the only morphologic evidence of pernicious anemia.

The most marked effect on the symptoms was noted in those cases in which the patients were sickest and who had the smallest number of erythrocytes at the time treatment was started. The color of the skin rapidly changed from the usual lemon yellow to a simple pallor and later to normal, the icteric hue of the sclerotics usually disappeared in a relatively short time. The weakness, anorexia, dyspnea and edema usually subsided rapidly. Gastric symptoms ordinarily were relieved but not with such great regularity. The soreness of the tongue usually disappeared, and the diarrhea usually but not always, subsided.

A questionnaire was sent to twenty-eight of the forty-six patients, of whom twenty-six answered more or less completely. Those to whom a questionnaire was not sent had been treated in the hospital so recently that such a procedure seemed useless, or else they were still under observation in the hospital. Nineteen patients reported regular and seven irregular use of the diet. Twenty-two reported no trouble in taking the gastric material and four slight trouble. One patient reported himself to be well and twenty-five reported themselves to be improved. Eight stated that they had had diarrhea at some time before treatment whereas eighteen had none. Of these eight patients, four were well and the condition of four had improved. One patient reported that weakness had disappeared, twenty-one that weakness was less marked, one that the weakness was the same as before and three did not make a statement in regard to weakness. Eighteen patients reported soreness of the tongue at some time before treatment and eight that their tongues never had been sore. Nine of

the eighteen were well after treatment, seven were improved, and two were the same as before. Eighteen patients reported that the appetite had been normal since treatment, five that it was improved, and three that it was the same as before. Twenty-three patients reported no relapse, whereas three patients reported having had a slight relapse while under treatment. Seven reported normal activity, ten restricted activity, and eight that they were not working, one did not report in regard to activity.

three that it was the same as before, and none that it was worse. Nineteen reported that they had suffered from lack of control of the limbs in walking before treatment. One patient reported disappearance of this symptom, and twelve patients its improvement, six were the same as before, and none were worse since treatment was instituted. The figures as to lack of control of the limbs are probably much too high as to incidence. It is probable that in some of these the supposed lack of control was due simply to weakness. Patients who had

* On the sixteenth day of treatment 26.2 per cent of erythrocytes developed

The effect on nervous symptoms has been less striking than that on the blood and general condition. In many cases the numbness and tingling has been improved, in some it has been abolished. Twenty-two patients have reported, by answers to questionnaires, that they had these symptoms before treatment, four have reported that they did not have them. Following treatment, five of these patients were rid of their paresthesia, fourteen reported that it was improved,

true psychosis have not been treated, but minor mental symptoms have seemed to improve with treatment of the condition. In one case, loss of libido was marked before treatment, whereas libido was exaggerated after treatment.

Fractional analysis of gastric content after a test meal has been made in all cases before treatment. Achlorhydria was present in all. In eleven cases a test of gastric acidity after injection of histamine was made.

before the patient left the hospital or at a later date. Free hydrochloric acid had not returned, nor was total acidity significantly increased in any case as the result of treatment.

Of the thirty-one cases in which the proportion of eosinophils was estimated both before and during, or after, treatment, in only ten was a higher percentage of eosinophils found during or after treatment than before. In only two cases was the increase so great that it appeared likely to be due to the treatment. The percentage of eosinophils was not as markedly increased in any case as it was by the feeding of raw liver. These data are not entirely in accord with those of Wilkinson, who reported that eosinophilia occurs after the use of gastric tissue. The absence of marked eosinophilia is additional evidence of the freedom from intestinal parasitosis, including trichinosis, among patients who use the raw material.

In order to investigate the possible transmission of parasites by the feeding of raw gastric tissue, the stools have been examined in most instances before, during and after the administration of the raw material. A parasite has not been found in the stool after treatment in any instance in which it was not present before. There is no parasite which inhabits the cavity or wall of the stomach of swine that is pathogenic for man, so far as I am able to determine. Trichinae do not occur in the gastric wall of swine. No patient is known to have contracted the porcine type of undulant fever as a result of the administration of raw stomach of swine.

COMMENT

Results with the different preparations of gastric tissue have been similar. However, not enough patients have been given pylorus alone, fundus alone, mucous membrane alone (with and without other meat), or whole stomach except mucosa to justify a statement that the effect of any of these fractions is exactly similar to that of whole stomach. In the cases in which mucous membrane alone was given, in two cases unaccompanied by other meat and in six with other meat, the response was satisfactory, also, in one case in which whole stomach except mucosa was given, a satisfactory effect was produced without the use of other meat. The dried material has the advantages of being easily available in city or country and of being of smaller bulk, but it has the disadvantage of being higher in price. The raw material has the advantage of being lower in price, and, to some patients, of being better in taste, but it has the disadvantage for some rural patients of being somewhat difficult to obtain and to keep. However, for rural homes, the invention of a cheap, practical refrigerator, operated by a kerosene flame, has now made the latter objection a minor one. Comparison of results with the different preparations and different amounts will be made the subject of a later contribution. The results with 240 Gm. of raw whole stomach make it appear that this is the average curative dose. Of desiccated hog stomach the curative dose usually was from 20 to 40 Gm., ordinarily about half the curative dose is required as a maintenance dose.

Ten patients had at some time been treated with liver, six with liver extract, and seven with both, either elsewhere or at the Mayo Clinic before institution of the treatment with gastric tissue. In almost all instances, however, the treatment with liver had been discontinued sufficiently long before the feeding with gastric tissue had been begun to make it relatively certain that none of the results obtained was a remnant of those following treatment with liver.

Among patients who answered the questionnaire, three had taken some liver since they had gone home, one patient, half a pound (225 Gm.) each day for two weeks while unable to get the gastric tissue, one, three slices a week, and one, a quarter pound (110 Gm.) every other day. Of course, in evaluating the results of feeding gastric tissue, one must be certain that the patient is not taking liver or its extract in any considerable amount.

No other treatment that is known to influence formation of blood was used in any instance, except two transfusions in one case, a diet rich in vitamins but containing no liver in two cases, and dilute hydrochloric acid in two cases. In one case in which moderate doses of liver extract had been taken for two years, with little improvement, there was seen a rapid increase in reticulated erythrocytes to 35.6 per cent, and a comparable increase in erythrocytes when raw stomach was fed. In another case, in which liver extract had been given for two years, with good results until recently, when there was a relapse, treatment with raw stomach is being given with satisfactory results. On the other hand, in one case there was poor response to desiccated hog stomach and good response to administration of liver extract.

The increase in percentage of reticulated erythrocytes and mature erythrocytes and the improvement in the general and neurologic symptoms are similar and apparently equal to those obtained by feeding liver or liver extract. The material also apparently has a mild effect of stimulating formation or liberation of platelets and leukocytes.

SUMMARY

Sixty patients who have pernicious anemia have been treated with gastric tissue of swine or with tripe. Two of those were given gastric tissue of swine after virtual failure with tripe, and tripe constituted the sole form of gastric tissue given to two. Forty-six of the patients have been carefully studied under observation in a hospital. Raw and dried preparations have given approximately equivalent results. The mucosa, the remainder of the stomach after the mucosa was removed, and whole gastric wall were used separately, and each proved effective in the cases treated. The presence of muscle meat was not required to obtain results in the two cases treated with mucosa without muscular coat or other muscle meat. Fundus and pylorus, each used separately, produced satisfactory but not equal results. The effects on the reticulated erythrocytes, mature erythrocytes, hemoglobin and leukocytes are similar to and apparently equivalent to those obtained by feeding liver or liver extract. The effects on the general and neurologic symptoms are apparently about the same as those obtained with liver or its extract. All patients so treated are alive so far as I know.

Challenging Civilization—The behavior problems of children are not to be considered as essentially mental nor as primitive evidence of mental disability or disease. In some ways the delinquent is one of the challenging factors of civilization. He is an indicator of communal maladjustment. His problems are the problems of the community. He is striving for personal satisfaction and harmony which in some way are at variance with the standards of the community. There are times, however, when the delinquency is wrong but the delinquent is right just as there are times when the punitive action of a community may be right but the community itself may be ethically wrong.—WILEY S. BEHAVIOR PROBLEMS OF CHILDREN with Special Reference to Delinquency. *Am J Dis Child* November 1930.

THE TREATMENT OF SECONDARY ANEMIA

FURTHER OBSERVATIONS *

JOHN H. POWERS, M.D.
AND
WILLIAM P. MURPHY, M.D.
BOSTON

This report deals with the comparative merits of iron, whole liver, liver extract and various combinations of these substances in the treatment of patients with anemia due to chronic hemorrhage or chronic chlorosis.

These two interesting types of secondary anemia frequently escape both recognition and treatment. The former is the result of the persistent loss of small amounts of blood over a long period of time. Such patients usually seek surgical advice because of menorrhagia or bleeding from the intestinal tract. The second type is not associated with any recognizable hemorrhage but occurs in young or middle-aged women and is characterized by a relatively low level of hemoglobin with an essentially normal red blood cell count.

Since the publication of a previous paper,¹ a new and more accurate method of studying anemia, recently

Chart 1 (case 1, table 1).—A graphic representation of the effect of iron on the blood of a patient with chronic secondary anemia. The double vertical line at the left of the chart indicates the beginning of treatment with iron.

utilized by Murphy, Lynch and Howard,² has been employed in this investigation. These authors used

Kennedy's³ procedure for determining the amount of iron contained in whole blood and found that this factor remains within singularly narrow and standard limits for normal adults. Any reduction of the blood iron below this level is indicative of anemia and, in fact, may be present before other symptoms can be detected. Consequently this factor is regarded as the most accurate criterion that has yet been devised for evaluating the true status of a patient with secondary anemia.

Chart 2 (case 11, table 2).—This patient was treated with iron and whole liver.

METHODS OF STUDY

Twenty-four patients were observed. For the purpose of comparative studies they were divided into four groups of six each. The patients in the first group received iron alone in the form of pills of ferrous carbonate, U S P, 18 Gm daily. The second group received iron plus whole liver, from 100 to 240 Gm daily. The third group received liver extract⁴ alone (three vials daily) for from three to seven weeks, after which iron (18 Gm) was administered in conjunction with the liver extract. The patients in the fourth group, after a similar control period on liver extract alone, were given in addition to the extract relatively small amounts of whole liver (from 90 to 120 Gm daily) to determine whether or not these substances exert any synergistic effect on each other. Whipple⁵ has suggested that small amounts of whole liver when given with liver extract may have such an effect.

The blood of each patient was studied at approximately weekly intervals by the following methods. Test tubes were prepared by evaporating to dryness therein 2 cc of a 16 per cent solution of sodium oxalate. Ten cubic centimeters of venous blood was withdrawn and placed in one of these prepared tubes, which was gently tilted back and forth several times to insure complete solution of the oxalate. (At this point in the procedure

it was considered important not to shake the tube in order that hemolysis and the formation of air bubbles might be avoided) Standardized pipets were filled from this oxalated blood and the erythrocytes were counted in standardized chambers Determinations of the percentage of hemoglobin were also made from this sample by the method of Sahli as modified by Osgood and

The patients who received iron alone or in combination with whole liver improved most rapidly The erythrocyte count, the percentage of hemoglobin, and the iron content of the blood responded promptly after treatment was instituted (tables 1 and 2) Improvement was persistent and constant until all three factors had attained their normal levels In the inter-

Haskins ⁶ The content of iron was determined by the procedure suggested by Kennedy, ³ because of the advantages of this method over that of other investigators

RESULTS

The results obtained by each method of treatment are tabulated separately A typical case in each group is presented in graphic form in the accompanying charts

⁶ Osgood E. E. and Haskins H. D. A New Permanent Standard for Estimation of Hemoglobin by the Acid Hematin Method J Biol Chem 57: 107 (Aug) 1923

pretation of the iron figures, 37 mg of iron per hundred cubic centimeters of blood may be regarded as the lower limit of normal ²

The patients who received liver extract alone showed no appreciable change in the percentage of hemoglobin or the blood iron In a few instances the erythrocyte count improved slightly After the addition of iron, however, all three factors increased in a very satisfactory manner (table 3) When the liver extract was supplemented by small amounts of whole liver, improvement was apparent but less striking than when iron was

used in conjunction with the extract (table 4) In tables 3 and 4 the first group of figures in each case represents the changes in the blood that occurred in the interval during which liver extract alone was administered The second group records the improvement that followed the addition of either ferrous carbonate or whole liver The effect of iron or of liver was not increased by the simultaneous administration of liver extract

Chart 3 (case 13, table 3)—This patient was treated with liver extract and iron. The single vertical line at the left indicates the beginning of treatment with liver extract. Marked improvement is apparent after the administration of iron (indicated by the double vertical line).

Although the observations on the percentage of hemoglobin and the red blood cell counts are of considerable interest, the figures for blood iron offer a much more accurate criterion for evaluating the results than do either of the other two factors. When the iron content of the blood failed to increase from week to week under appropriate treatment, and in some instances

Chart 4 (case 19, table 4)—This patient was treated with liver extract and whole liver. The single vertical line at the left indicates the beginning of treatment with liver extract. The addition of liver is indicated by the double vertical line.

actually decreased the cause was usually apparent in the fact that the patient had had a recent menstrual period. In other words, this determination is sufficiently sensitive to detect even the slight temporary anemia that occurs during the normal menstrual cycle. That such variations in the blood iron actually do occur under

these circumstances is apparent from the foregoing observations.

CONCLUSION

Patients with secondary anemia due to chronic hemorrhage or chronic chlorosis respond very favorably to treatment with iron in the form of ferrous carbonate. They respond equally well when whole liver is given in conjunction with iron.

Liver extract is of no value in the treatment of these types of chronic secondary anemia. The effect of iron or of whole liver is not increased by the simultaneous administration of liver extract.

AGRANULOCYTOSIS

REPORT OF A CASE WITH A TERMINAL GAS BACILLUS INFECTION *

OTIS S. WARR, M.D.
MEMPHIS, TENN.

During the eight years since Weiner Schultz of Berlin first gave the name "agranulocytosis" or "agranulocytic angina" to a group of cases that have a severe ulcerative and gangrenous stomatitis and a neutrophil leukopenia with a relative lymphocytosis, many cases have been reported, chiefly by German and American observers. The literature dealing with this peculiar phenomenon has been repeatedly and comprehensively reviewed to date. Many clinicians regard agranulocytosis as a hitherto undescribed disease entity, but numerous writers maintain that the picture described by Schultz is not specific and hold to the view that so-called agranulocytosis simply constitutes a type of leukopenic reaction to an overwhelming infection. Whatever the view, there are features in the reported cases sufficiently striking, uniform and frequent to warrant separate group consideration.

Cases are common to the two sexes with an incidence of about 70 per cent in females, and they occur in all age groups, the average age being about 40 years. The majority of cases have an acute onset in a period of good health. There is a high continued fever from 102 to 104 F, and profound prostration is common. Other prominent symptoms are sore throat, malaise, chills and dysphagia. Necrotic or ulcerative processes have been observed almost constantly in various parts of the oral cavity, and not infrequently lower in the gastro-intestinal tract, in the cervix and the vagina, and on the cutaneous surfaces. Occasionally the spleen and liver are enlarged. In about one half of the cases, jaundice develops as the disease progresses. Examination of the heart and lungs is negative in the beginning, but death is often preceded by a terminal pneumonia. A terminal gas bacillus infection, such as occurred in the case here reported, appears to be entirely unique. However, Talley and Griffith¹ record a case in which a clinical diagnosis of gas bacillus infection was made and *B. anthracis* serum given on account of a rapid swelling of the hand and arm with bluish discoloration and formation of vesicles. The infection apparently started from a cut in the palm of the hand received before admission. Smears and blood cultures failed to

1. Talley, J. E. and Griffith, G. C. A Discussion of Six Cases of Agranulocytosis. *Am. Clin. North America* 13: 1079-1090 (Jan.) 1930.

confirm the diagnosis. Trace² also mentions a case in which gas bacillus infection of the arm was suspected but not proved. The course of the disease is usually acute and death occurs in from four to eight days, the extremes being from two to forty-two days. Periods of temporary improvement sometimes take place, but death may be expected to ensue in approximately 90 per cent of the cases.

The outstanding pathognomonic characteristic of this highly fatal disorder is the unusually striking blood picture. A leukopenia at the onset of the disease is the rule, the total leukocytes often being reduced to 1,200 or less per cubic millimeter. Polymorphonuclear leukocytes either are entirely absent or constitute less than 6 per cent of the white cells. The lymphocytes are always relatively increased, sometimes up to 100 per cent. An important feature of the blood examination is the maintenance of a normal red cell count and hemoglobin percentage. A few cases develop a mild secondary anemia late in the disease. The platelet count also is usually within normal limits and the bleeding and coagulation time is normal. Blood cultures are generally sterile, and in the few cases with positive blood culture (about 10 per cent) there is no uniformity of invading organism.

In this disease the bone marrow as well as the blood picture is characteristic. It is usually pinkish or red. Lymphoid cells are present mainly, and erythroblasts and megakaryocytes are normal. Granulocytic elements are almost completely absent. Cell-poor marrow is a fairly consistent finding at autopsy, but the hypoplasia of granular cells has also been found in bone marrow during the height of the disease and is therefore not a terminal event.

The etiologic agent has as yet not been determined. Whether the condition is the result of endocrine disturbance, whether it belongs in the groups of the acute leukemias or whether it is an infectious disease that especially affects the granulocytic system remains a matter of wide conjecture. A variety of organisms has been recovered from the blood stream and local lesions, but in many instances pathogenic organisms have not been found. From the blood, hemolytic streptococci, staphylococci, *Bacillus pyocyaneus*, *B. coli*, pneumococci and *Streptococcus viridans* (Cannon) have been recovered. From oral lesions, Klebs-Loeffler bacilli, Vincent's spirochetes and fusiform bacilli, pneumococci, *B. pyocyaneus* and streptococci of various types have been isolated. However, no definite causative factor has been determined, as the bacteriology is without uniformity, and the lack of demonstrable blood stream infection becomes a significant negative finding. The disease not infrequently follows the extraction of teeth, and a few cases have followed antisyphilitic treatment with the arsphenamines.

In the differential diagnosis of agranulocytosis, acute poisoning, such as from arsenic, benzene, thorium and roentgen rays, acute leukemia and leukemic leukemia, unusual cases of anemia, and sepsis may all produce similar anatomic and blood changes. In its early stages the disease often prades under the guise of diphtheria, Vincent's angina or so-called septic or streptococcal sore throat.

Therapy is of necessity largely symptomatic, since the etiology remains obscure. Local treatment is directed toward alleviation of sore throat and pain by

frequent gargling and various antiseptic applications. General treatment includes the usual supportive care and an attempt to maintain nutrition. There is no specific therapy, but frequent blood transfusions, intra venous administration of neoarsphenamine, and stimulating doses of x-rays are used in an attempt to stimulate the bone marrow.

In the foregoing paragraphs the salient features of this highly fatal malady are briefly mentioned. Whether agranulocytosis represents a particular biologic type of hematopoietic reaction to infection or is a distinct disease entity, it certainly robs the body of its defensive mechanism and leaves it an easy prey to severe infection, as the accompanying case report illustrates. The case here presented conforms in its clinical and pathologic features with the majority of the reported instances of agranulocytosis from its initial onset up to the onset of the terminal gas bacillus infection four teen hours before the death of the patient. From that point on, it is seemingly without parallel in the literature.

REPORT OF CASE

History—Mrs. H. J. H., aged 26, married, had been in good health until the morning of June 29, 1930, when she awoke complaining of sore throat, general itching and soreness. During the day her temperature rose to 101 F. For the next two days her symptoms were unchanged. The fourth day she felt better, her temperature was normal, and she was able to be up part of the time although she still complained of sore throat. The next day her temperature was 103 F., her throat was more painful and she was greatly prostrated. From this time on her condition grew progressively worse. When she was brought to the hospital on the seventh day, her temperature was 104 and her pulse was 130. The lungs were apparently normal. The abdomen was moderately distended and the spleen and liver were not palpable. There was no jaundice. In addition to the sore throat she now had discrete superficial ulcers on the hard palate and around the gum margins. Smears from these showed the presence of Vincent's spirilla and spirochetes. The blood count was as follows: hemoglobin, 73 per cent; red blood cells, 4,200,000; white blood cells, 2,975; polymorphonuclear neutrophils, 8 per cent; small lymphocytes, 68 per cent; large lymphocytes, 3 per cent; metamyelocytes, 1 per cent. The next morning the leukocytes were 1,450, with polymorphonuclear neutrophils, 4 per cent and lymphocytes, 96 per cent. Blood platelets were 130,000.

She was now given a light roentgen treatment over the long bones, the sternum and the jaws. A few hours later she was given a transfusion of 500 cc. of whole blood without any reaction resulting. Just before the transfusion she was given 0.3 Gm. of neoarsphenamine intravenously.

Her temperature ranged from 104 to 105 F. all that night and about 5 a. m. she began to complain of severe pain in the upper part of the right thigh. The pain was of such severity that a gram (0.065 Gm.) of pantopium hydrochloricum in two hours had no effect, and she was finally given 1/100 grain (0.6 mg.) of scopolamine and one half grain (0.03 Gm.) of morphine before she was quieted. Examination of the thigh at first showed no swelling or discoloration but it was tender to deep pressure. There was no change in the condition of the mouth. The blood count was now as follows: hemoglobin, 85 per cent; red blood cells, 4,380,000; white blood cells, 1,850; polymorphonuclear neutrophils, 35 per cent; lymphocytes, 65 per cent. Another blood transfusion was now decided on but was not given for, on intertyping the blood with that of nine prospective donors a most unusual phenomenon was observed. The patient's cells were rapidly and completely hemolyzed by the serum of each and every donor tried while the donor's cells were not affected by the patient's serum.

About eight hours after the onset of the pain in the hip an area of bluish discoloration about 4 by 8 inches appeared on the outer aspect of the thigh just above the knee. In a little while a similar area, though smaller, appeared on the calf. With the appearance of these discolorations the thigh began

² Trace, I. M. Agranulocytic Angina. Illinois M. J. 55: 36-38 (Jan.) 1929.

to swell, and in a short time the entire leg was greatly swollen and had become cold and stiff. No pulsations could be felt below the femoral artery. Soon after the swelling appeared definite crepitation could be made out on deep pressure over the discolored areas. A roentgenogram of the thigh showed no bony changes, but the soft tissues showed air infiltration both deep and superficial. At the time of the patient's death, fourteen hours after the onset of the pain, the crepitation and discoloration had extended upward to the level of Poupart's ligament, the crest of the ilium and the upper margin of the right gluteal muscles posteriorly. In the meantime, large purplish blebs had appeared on the posterior aspect of this thigh.

Autopsy—The autopsy was done about two hours after death. The essential observations were as follows. There were dirty grayish ulcers around the gum margins of the right lower molar teeth, on the hard palate and on the tonsil pillars. The lungs were normal, except for a small area of pneumonic consolidation in the right lower lobe. The heart was normal except that a considerable amount of gas escaped when the right auricle was punctured to obtain blood for culture. The blood obtained was frothy. The intestines were moderately distended but there was no evidence of peritonitis. In the lower end of the ileum about 3 inches from the ileocecal valve there was a dry grayish, somewhat elevated and necrotic-looking Peyer's patch about 1 inch in diameter. The serosa covering it was quite red but no evidence of perforation could be found. The adjacent mesenteric glands were not enlarged. On the anterior wall of the ampulla of the rectum there were two superficial grayish ulcers about 1 cm in diameter. The serosa covering these was also greatly injected but again no evidence of a perforation could be demonstrated. Directly opposite these ulcers on the adjacent posterior wall of the uterus was a similar circumscribed area of redness. The right tube and ovary were enlarged and crepitant. The left adnexa were normal. The uterus was normal in size and appearance and the endometrium was normal. No ulcerations were found in the vagina, and the cervix was smooth and normal. The liver was normal in size and appearance. The spleen was about twice normal size, was soft and the cut surface was such as is usually seen in the presence of an acute infection. A specimen of bone marrow from the right femur was pale red in appearance and smears showed a remarkable scarcity of cells. No polymorphonuclear cells of any kind were seen and only an occasional myeloblast.

The most remarkable changes were found in the right leg which was greatly swollen and which had apparently increased in size after death. The outer aspect of the thigh extending to the crest of the ilium had a mottled bluish appearance. On the posterior surface were two large blebs, each about 3 inches in diameter, and both surrounded by large irregular areas of ecchymosis. These blebs contained a clear wine colored fluid. When the leg was punctured there was an audible escape of gas, which readily ignited. A careful search was made for a portal of entry for the gas bacillus but the skin was intact everywhere. The muscles had the peculiar dark bruised appearance usually seen in cases of gas gangrene. Cultures were made from the throat, the heart blood, the blebs on the thigh and the muscles of the thigh, all of which showed the presence of the gas bacillus in large numbers.

COMMENT

This case is unique first, because of the terminal gas bacillus infection and secondly, because the portal of entry for the gas infection was never determined. There was certainly no reason to believe that the gas bacillus entered through the skin. Since this organism is commonly found in the intestinal tract a careful search was made for a portal of entry here. Assuming that it entered through the intestinal ulcers this would not explain why the gas infection was practically limited to the right leg. The absence of vaginal ulcers and of any cervical or uterine lesion is sufficient to exclude the genital tract as the primary source.

20 South Dunlap Street

THE CHEST IN RACHITIC CHILDREN

A ROENTGENOLOGIC STUDY *

RALPH S. BROMER, M.D.

Roentgenologist to the Children's, the Episcopal and the
Orthopedic Hospitals
PHILADELPHIA

During the past five years all cases coming to the roentgen laboratory of the Children's Hospital for examination of the chest that showed signs of rickets, such as a rosary or a deformity of the chest, have been collected for study. Information on the incidence of pneumonia and atelectasis, the type of pneumonia usually encountered, the prognosis and the differential diagnosis of pneumonia and atelectasis was especially sought. In cases of suspected pneumonia in infants and young children showing a rachitic rosary with deformity of the chest, the differentiation between atelectasis and pneumonia is sometimes difficult. An effort was made to study the usual roentgenographic distribution of atelectasis and to reach some conclusion that would be an aid in the differential diagnosis.

Seventy-eight patients were studied, divided into three groups: the first, thirty-one in number, which showed a rosary in the roentgenogram but which exhibited at no time any evidence of pneumonia or a chest deformity; the second, twenty-four cases which showed a rosary in the roentgenogram and presented roentgenographic and clinical evidence of pneumonia but with little or no chest deformity; and the third group, twenty-three cases, with marked chest deformity with or without pneumonia. In the first group there were twenty-four Negro and seven white children, three of the latter being Italians; in the second, there were twenty-one Negroes and three Italians; in the third consisting of twenty-three children, all were Negroes.

In the first group, ranging from 5 months to 4 years of age, a large proportion were admitted to the hospital with a diagnosis of acute bronchitis and showed no evidence in the roentgenograms of any pneumonic process. Two deaths occurred in this group: one from intussusception and the other from an unknown cause, it being impossible to obtain an autopsy. In several cases, although no definite depression of the chest was present, there were shadows running parallel to the heart and mediastinal shadows, which were suggestive of the so-called atelectatic strips later to be described. No deaths were directly or indirectly attributable to rickets and the study of this group bears out the statements of Hess,¹ Park and Howland,² and others that rickets with lesser chest changes is not dangerous to life.

In the second group, those cases showing a rosary with little or no chest deformity, the ages of the children ranged from 5 to 26 months. No cases were included in this group in which there was a definite recorded note of well marked chest deformity. Of the twenty-four patients five died, a mortality of 20.8 per cent. Fourteen showed roentgen evidence of bronchopneumonia and ten showed lobar pneumonia. Of the lobar pneumonia patients two had a complicating

emphyema. The cause of four deaths was bronchopneumonia and the fifth was caused by lobar pneumonia followed by emphyema.

The last group included patients showing marked deformity either clinically or in the roentgenograms. Several, with very little actual deformity apparent in the roentgenograms, presented a markedly streaked or moth-eaten appearance of the ribs with clinical notes of dyspnea, respiratory difficulty or apparently deficient aeration of the lungs. Of the twenty-three patients in this group all of whom were Negroes twelve died, a mortality of 52.1 per cent. Thirteen had clinical and roentgen evidence of bronchopneumonia and three had lobar pneumonia. Of the patients with bronchopneumonia, nine died; of those having lobar pneumonia, two died. The ages ranged from 5 to 15 months except in one case of lobar pneumonia, which occurred in a child of 4 years who had rickets in an advanced stage of healing, with a persistent chest deformity. The recurring death was apparently caused, as stated in the clinical record, by deficient aeration of the lungs, depression of the chest wall and extreme abdominal distention. An autopsy was obtained in this case.

When the chest was opened at autopsy, it was found to be very narrow and constricted in its anterior portion. This narrow anterior part was occupied almost entirely by the heart, which lay in a central position. At about the middle of the ribs was a forward angulation, the angle being so acute that practically no space was left in the pleural cavity. About two thirds of the left lung was dark, bluish and of rubbery consistency, due to atelectasis. The surrounding edges anterior and posterior, were emphysematous. The edges were sharply demarcated from the emphysematous portions. The atelectatic areas corresponded with the depressions formed by the bent-in chest wall at the site of the rosary. The entire middle lobe of the right lung was atelectatic. No mention was made in the autopsy record of the presence of any areas of bronchopneumonia.

THE RACHITIC CHEST

The deformities of the thorax produced by rickets have been fully described by Hess, Park and Howland and others. The earliest change noted in the roentgenogram is the beading of the ribs or the rosary, which is shown by the saucer-shaped margins of the sternal extremities. This sign cannot always be used as evidence of early rickets. Hess has pointed out that the rosary is not apparent in the roentgenogram until rickets is often well advanced. Again, the rosary is not always caused by rickets alone. Hess and Ungcr³ have shown that it can be caused by infantile scurvy, but in the latter it is angular rather than round and knobby as in rickets and is due to actual infarctions at the costochondral junctions. The beading in rickets is usually manifested in the roentgenogram by more or less prominent cupping, causing the saucer depression of the anterior chondral extremities of the ribs. These shadows must not be mistaken for infiltration and abnormal densities in the lungs themselves.

In mild cases this is the only noticeable change. In the severe cases, before healing has begun, the ribs have a moth-eaten streaked appearance, the cortex is much rarefied, and it casts only a faint shadow in the roentgenogram. It seems quite probable that this extreme rarefaction is the cause of the pliability and yielding of the chest wall, which can be demonstrated when pressure is

exerted on it during clinical examination. In my series of cases it was difficult to prove this, as the presence or absence of pliability of the chest wall was not a routine observation on all of the clinical records.

The chest may be misshapen in several different ways. In the majority of cases there was no deformity of the chest wall, merely an uncomplicated rosary being present. In a few patients, in addition to the rosary, the ribs were curved inward at the level of the seventh or eighth ribs. This was usually bilateral. In other cases the upper half of the thorax had an appearance as though compressed while the lowermost ribs flared out; the anterior portions being affected, and their parallel arrangement was lost. The interspaces became progressively wider as the lower ribs were reached. In other patients the chest remained narrow throughout its length. Pathologic fractures of the ribs were frequently found, the displacement of the fragments producing an irregularly indented appearance of the thoracic cage.

In very severe cases the chest may be so deformed that pressure is exerted on the lungs and the thoracic blood vessels leading to disturbances in respiration and circulation. Park and Howland² have described such deformities occurring in Negro babies, a condition which constitutes a grave menace to life. They studied twenty-two children between the ages of 8 months and 4½ years. All the children of their series exhibited well marked deformities of the thorax. In addition there was present what is considered by the authors the essentially dangerous element, great weakening of the chest wall.

They describe the shape of the chest wall as similar to a blunt wedge the sternum and the adjacent portions of the costal cartilages corresponding to the narrow end of the wedge. Deep bilateral hollows in the chest wall correspond to the sites of the costochondral junctions. The deepest part of the depression lies at the sixth or seventh costochondral junctions. The depression on the right side is in most cases larger than the one on the left, which they think is caused by the fact that the heart furnishes support to the thoracic wall on the left side. In the less severe cases there may be no depression on the left side but only flattening of the normal arch of the chest. The posterior angles of the ribs that form the depression are much more bent than normal and form a rounded ridgelike elevation 3 or 4 cm. broad, which projects laterally and sharply separates the back from the anterolateral surface of the chest.

This deformity, however, is not believed by them to be the essentially dangerous condition. The weakness of the chest wall is the real menace to life. They point out that the diaphragm can act only to advantage when its points of attachment are fixed and remain firm. In the weakened thorax of rickets, the diaphragm expends part of its energy in drawing its own points of attachment inward. In so doing it diminishes the extent of its descent and impairs, by just so much, its powers to increase thoracic space. Owing to the deformity of the thorax, the diaphragm must tend to remain, even in expiration in a state of partial inspiratory contraction. When inspiration takes place it must commence its contraction from a position of partial contraction and is able, therefore, to accomplish only part of its work, which, as a muscle in a state of normal relaxation at the outset, it would be capable of accomplishing. It is quite possible, they also believe, that the contractile power of the diaphragm is impaired as a result of the rickets itself.

³ Hess, A. F. and Ungcr, L. J. Scorbatic Beading of the Ribs. *Am. J. Dis. Child.* 19: 331 (May) 1920 quoted by Hess (footnote 1)

As a result of this impairment of the function of the diaphragm due to the weak chest wall, Park and Howland believe that a definite clinical picture results. The temperature of the patients with this condition is not greatly elevated and sometimes remains normal, the respirations are greatly increased, never less than 60

Fig 1 (group 2)—Extensive bilateral bronchopneumonia occurring in a patient having only a mild rosary with no marked rachitic involvement of the ribs

and sometimes rising to 80 and 100 a minute. The leukocyte count is low. The presence of infection is entirely subsidiary, the loss of rigidity of the thoracic frame, the result of the rickets, is the dangerous element. The autopsy record just quoted is an excellent illustration of this type of case.

ROENTGEN APPEARANCE OF THE RACHITIC CHEST

In the first group of cases the rosary was shown in the roentgenogram in the usual manner, the width of the cup-shaped sternal ends of the ribs depending on the degree of rachitic involvement. In three of the cases there were indistinct striplike shadows of increased density running upward and downward from each hilus. Since obvious deformity of the chest was not present, these shadows could not be regarded with certainty as the usual manifestations of atelectasis. As healing progresses, the cup-shaped ends become denser and more clearly defined.

In the second group of cases, in which bronchopneumonia was present in fourteen and lobar pneumonia in ten, the usual roentgenographic changes of each type were found. In four cases of lobar pneumonia involving the right upper lobe, definite retraction of the heart to the affected side occurred. This displacement of the heart was regarded as an illustration of pneumonia combined with atelectasis, as described by Griffith⁴ Thoenes⁵ and others and occurs in normal children who contract pneumonia. None of the cases of this group showed changes that could be regarded as characteristic of the atelectasis due to rickets.

⁴ Griffith I. P. C. Displacement of the Heart in Pneumonia in Children. *Am. J. M. Sc.* 1-4 448-452 (Oct.) 1927.
⁵ Thoenes Monatschr. f. Kinderh. 23 33 (July) 1922 quoted by Griffith ref 4.

In the roentgen picture of the third group of my cases, the ribs were thin and often had the streaked and rarefied appearance previously referred to which indicates weakness of the chest wall. Pathologic fractures frequently caused indentations of the thoracic wall. Scoliosis and kyphosis often increased the deformity of the chest. Of the twenty-three patients of this group, seven definitely showed the central position of the heart such as occurred in the case just quoted in which a postmortem examination was made. Often the heart seemed proportionately larger than the chest. Parallel with the sternum, usually running from the second or third dorsal vertebra, were striplike shadows of increased density in each lung which were caused by atelectasis. These shadows in some cases coincided with those of the rosary, in others the rosary seemed to lie at the outer side of the atelectatic areas. Faulty technique, deviation of the target from the midline of the chest, or rotation of the child on the film can cause such a shift in the positions of the rosary and the atelectatic areas. In many cases the shadow of the atelectatic strip was merged on the left side with the shadow of the heart and so was lost to view.

Scattered throughout the lungs beyond the atelectatic strips were small, more or less circumscribed areas of increased density which were due either to small areas of atelectasis or to small areas of bronchopneumonia. It is practically impossible from a roentgen standpoint to differentiate between these two conditions. Many of the cases of bronchopneumonia showed large dense areas due to confluence of numerous lobular areas of involvement. When a child has a history of tuberculous contacts, has a positive tuberculin reaction and has other signs of tuberculosis, it is very difficult to differentiate between bronchopneumonia or atelectasis

Fig 2 (group 3)—Marked rosary, moderate rachitic involvement of the ribs. Extensive bronchopneumonia and atelectatic strip, right lung. Marked deformity of the chest, especially on the right side, shown on clinical examination.

and tuberculosis. One patient of the third group had in addition to very marked signs of rickets, shown both on clinical examination and in the roentgenogram, a positive tuberculin reaction and also a definite history of contact with tuberculous relatives.

The usual roentgen signs of atelectasis cannot be relied on in cases of rachitic deformity. The heart can be apparently retracted to the right side, as is the case in the typical roentgenogram of atelectasis occurring in the right lung, but this is usually caused in the rachitic chest by the central position which the heart assumes because of the deformity of the thoracic wall. The small scattered areas of atelectasis may be uniformly distributed throughout both lungs and so cause no deviation of the heart to either side.

As Park and Howland have stated the right side of the chest often showed in my series more deformity than the left. It is difficult to gauge accurately the amount of deformity of the chest when only a roentgen can be seen in the roentgenogram and no constriction of the upper chest wall, pathologic fractures or flaring of the lower ribs are present. This is true in roentgenograms in either the anteroposterior or lateral planes. Lateral views are useful in determining whether depression or bulging of the sternum is present. It is more common to find sternal deformities in the late stage of complete healing and they often may remain as residual deformities throughout life.

The change in the appearance of the rachitic chest after healing has begun is striking. This has been observed in cases in which cod liver oil has been given and especially, in my series of cases, in those children who receive ultraviolet ray therapy. The ribs and bones of the shoulder girdle lose their streaked appearance, the upper extremity of the humerus and the scapula show new zones of temporary calcification with well defined osteoid zones, the swollen sternal ends

does not increase the hazard when pulmonary infections occur. None of the patients in the first group, who had a mild or moderate rosary without apparent chest deformity, died from the effect of the rachitic process. Many were examined for a suspected pneumonia, but the roentgen examination proved negative and they were subsequently discharged from the hospital with a diagnosis of acute bronchitis. The mortality rate of

Fig. 4 (group 3)—Marked rosary and chest deformity. Autopsy showed central position of the heart, areas of atelectasis left lung, corresponding to the depression of the rosary. Atelectasis middle lobe of the right lung. Scoliosis and kyphosis.

Fig. 3 (group 3)—Marked rosary and chest deformity. Small area of bronchopneumonia upper right lung. Partial atelectatic strip left lung.

of the ribs cast denser and wider shadows, and even if the deformity remains the bones give an impression of greater strength. With this return of rigidity of the chest wall, the danger from respiratory infection is appreciably lessened.

CONCLUSIONS

The study of this series of cases shows conclusively that mild rachitic involvement of the chest, as has been stated by previous authors, is not dangerous to life and

the second group, which consisted of cases exhibiting a mild or moderate rosary with no deformity, does not seem to be greater than the usual rate found in the average patients admitted to hospitals with pneumonia showing no rachitic involvement of the chest, many of whom often have had prolonged treatment at home until they have reached a grave stage of their illness. The rate rises proportionately with the increase in deformity and especially with the degree of pliability of the chest wall. The case that came to autopsy in my series would seem to prove their statement that deformity and normal thoracic function are compatible, but the loss of rigidity of the chest will so seriously impair the normal function that any infection may prove fatal, however mild it may be. As healing progresses, the thorax regains its rigidity even though deformed and the death rate in this series was consequently much less in the children over 3 years of age. In fact no patients died in the series when pneumonia occurred after healing was well advanced. Rickets is of course well known to be especially prevalent in the Negro race, and almost the entire series was composed of Negroes. The third, or severe, group consisted entirely of Negroes.

The usual type of atelectasis due to rickets as described by Baetjer and Waters⁶ Park and Howland⁷ and others can easily be recognized in the roentgenogram by its characteristic location. The small scattered areas of atelectasis are indistinguishable from bronchopneumonia. The usual signs of atelectasis, as they

⁶ Baetjer, F. H. and Waters, C. A. *Injuries and Diseases of the Bones and Joints*. New York: Paul B. Hoeber, 1921.

occur when the normal chest becomes involved, are of no assistance in the diagnosis of rachitic atelectasis, because the latter is for the most part dependent on the degree of rachitic involvement of the ribs and the amount of deformity of the chest. The absolute differentiation between bronchopneumonia and atelectasis is not of great clinical importance from the standpoint of prognosis. The two are equally dangerous. The roentgenologist can aid the clinician in the prognosis of the probable outcome of the case, the gravity increasing in direct proportion to the degree of rachitic involvement, the deformity being the secondary consideration.

Bronchopneumonia occurs more frequently than lobal pneumonia and is of much greater frequency in the cases exhibiting severe involvement of the ribs and chest deformity.

ABSTRACT OF DISCUSSION

DR WILLIAM A EVANS, Detroit. A proper comprehension of all that has just been heard is dependent on a full knowledge of the mechanics of respiration—that is, what

Fig. 5—Marked rosary and chest deformity. Extensive rachitic involvement of the ribs. Fractures of the ribs. Central position of the heart. Scoliosis and kyphosis. Marked atelectatic strips both lungs. Patient died; no autopsy obtained. Probable bronchopneumonia complicating the atelectasis.

certain tissue changes may interfere with this mechanism or what intrathoracic changes may result from improper respiration. The production of all the pathologic signs described by Dr Bromer naturally follows if certain tissue defects are present and respiration is modified thereby. Thoracic deformities occur not primarily because the wall structures are weakened but because of the negative intrathoracic pressure. It is this negative intrathoracic pressure which explains the development of pectus excavatum or funnel chest and makes necessary devices to prevent caving in of the anterior thorax when operation is performed for such a deformity. Owing to this negative pressure the lung constantly clings normally to the thoracic wall and is separated only in the presence of local disease or of some mechanical force. The presence of atelectasis in the new born is explained in part by the insufficient increase in the size of the thorax which occurs at the inception of respiration and the opposite condition occurs when the thorax expands unduly for here one observes points at which the lung is not in contact with the chest wall although it is apparently expanded to its capacity. The high mortality in cases showing extreme weak-

ness of the thoracic wall can be explained by a condition simulating paradoxical breathing. In performing the operation of thoracoplasty, when a certain number of ribs are removed, the weakening of the thoracic wall may be so great that the lung on the operated side goes down in inspiration rather than out and out in expiration rather than down, thus bringing about an interchange of air between the two sides. Such breathing is dangerous and accounted for many deaths in the early days of massive rib resections. Then, too, the atelectasis may result from hypoventilation—the condition of incomplete aeration of the lungs. Muller's observations gave good support to this view. In twenty four operations for gallbladder disease or other abdominal condition, some degree of atelectasis or limited pulmonary consolidation was discovered in practically every case. The pneumonias associated with these terminal conditions result primarily from localized obstructions in the peripheral air passages—that is, atelectasis and pneumonia are closely related in their origin, as they are dependent on occlusions, atelectasis resulting first and then pneumonia developing in this subnormal tissue.

DR RALPH S BROMER Philadelphia. I am glad that Dr Evans brought out the mechanics of respiration as he did also that he brought out the prevalence of upper respiratory infection which Park and Howland have emphasized in children with severe rickets. If the new conception, that pneumonia is primarily an infectious atelectasis is fully confirmed there would be all possible chance for pneumonia to occur in these cases of rachitic atelectasis probably secondary to an upper respiratory infection. The degree of pliability of the chest wall is sometimes astonishing. I forgot to mention the presence of pathologic fractures in some of the slides occurring especially in the lower ribs. If negative pressure were exerted on these ribs I think that it could probably cause fractures, just as they are caused by outside or positive pressure.

SLIPPING OF THE LOWER FEMORAL EPIPHYSIS

JOSEPH I KURLANDER, MD
Orthopedic Surgeon, St. Joseph's Hospital (Lorain, Ohio)
CLEVELAND

In recent years considerable attention has been given to injuries of the upper femoral epiphysis, particularly to that type of injury known as 'slipped' epiphysis. Orthopedic literature contains a considerable number of articles on injuries and displacement of the upper femoral epiphysis. Likewise at practically every orthopedic conference or convention cases of upper epiphyseal injuries are demonstrated. At these meetings, however, I have never seen demonstrated nor heard mention of a case of injury to the lower femoral epiphysis.

Injury to the lower femoral epiphysis, especially avulsion with displacement, apparently is so rare that standard textbooks such as those of Albee,¹ Jones and Lovett,² and Whitman,³ make no mention of this type of injury. Scudder,⁴ in his book (1926) on fractures, states that separation of the lower femoral epiphysis is extremely rare and occurs in children about 10 years of age. He further states that half of these injuries are compounded, the common displacement being anterior. He also adds that if the vessels are torn (1926),

* Read before the Section on Orthopedic Surgery at the Eighty First Annual Session of the American Medical Association, Detroit, June 22, 1930.

2 Jones, Robert, and Lovett, R. W. *Orthopedic Surgery*. New York: William Wood & Co., 1929.

3 Whitman, Royal. *Orthopedic Surgery*. Philadelphia: Lea & Febiger, 1917.

4 Scudder, C. L. *The Treatment of Fractures*. Philadelphia: W. B. Saunders Company, 1926.

the popliteal) and there is much laceration of tissues, amputation should be performed. Bohler states that where the epiphysis is slipped anteriorly, it may be reduced by flexing the knee strongly. After reduction the knee is brought back to a 90 degree flexion. He also warns of the danger to the popliteal vessels.

An estimate as to the rarity of this type of injury may be adduced from the fact that in Cleveland, a city of about a million population with mixed diversity of industry, no surgeon with whom I have spoken recalls ever having seen a case of slipped lower femoral epiphysis.

Fig. 1 (case 1)—Condition before reduction

At the Cleveland City Hospital (1,000 beds), the attending radiologist recalls seeing but one case, and his memory is not clear as to exactly the type of displacement present. At St. Joseph's Hospital, Lorain, Ohio, with a population of 45,000, where a considerable amount of bone and joint traumas are seen, two cases of dislocation of the lower femoral epiphysis have been seen. It is evident, therefore, that complete avulsion and dislocation of the lower femoral epiphysis is extremely rare.

The lower femoral epiphysis is not united to the shaft until the twentieth year. Because of this late union of the epiphysis to the shaft injuries with dis-

placement may result to this epiphysis up to the twentieth year. It is therefore apparent that injuries to the discs of the lower femoral epiphysis before the age of 20 may result in premature arrest of ossification with a resultant greater or less shortening of the femur. It is entirely possible that by excessive stimulation the opposite may be true.

The capsule of the knee joint is attached to the femur just below the lower epiphysis and for that reason simple slipping of the epiphysis would probably not open up the knee joint.

This type of injury one would expect to see when the leg has been caught in a rapidly revolving carriage or wagon wheel.

REPORT OF CASES

The following are three cases which I am adding to the literature.

CASE 1—A white boy, aged 15, was tackled while playing football and was thrown forcibly to the ground. He does not remember the position of his knee in falling. He experienced immediate severe pain in the right knee joint, which was held in a flexion of 90 degrees and which could not be straightened out. He was removed to St. John's Hospital, where I saw him in consultation the following morning. Examination disclosed the right knee moderately swollen and tense and held in a flexion of 90 degrees. Attempts to manipulate the knee were impossible because of the sharp muscle spasm and pain. There appeared to be no deformity, although a slight bulging was apparent in the popliteal space. The pain seemed to be greater here. There was complete absence of the customary discoloration.

A roentgenogram (fig. 1) revealed a complete avulsion fracture of the lower femoral epiphysis with rotation and posterior displacement. Under ether-gas oxygen anesthesia, the displacement was reduced perfectly, as shown in figure 2, taken through the plaster cast. Reduction was accomplished as follows: The thigh was sharply flexed on the abdomen and the leg on the knee. In this position strong traction was made on the knee and leg until the epiphysis was heard and felt to snap into normal position. Without moving the knee or leg a plaster of paris cast was applied from the groin to the toes holding the knee in a flexion of 80 degrees. This cast was allowed to remain for four weeks following which it was removed and walking with crutches permitted, weight bearing being gradually permitted. The end results were perfect, within ten weeks the boy was playing basket ball.

CASE 2—A white boy, aged 10, fell and complained of a sharp pain in his knee, which he was unable to straighten. The attending physician was able to straighten the knee under anesthesia and applied a cast, which was permitted to remain for four weeks. The patient then came into the hands of another physician, who removed the cast and had a roentgenogram (fig. 3) made, which revealed the fact that there was an avulsion of the lower femoral epiphysis with marked anterior displacement. There was considerable callus formation and the epiphysis was uniting to the anterior shaft of the femur. At open operation this epiphysis was chiseled loose and replaced as near as possible to its normal bed. Unfortunately, the first roentgenogram is not available. Figure 4 shows the replacement, uniting to the femur with considerable callus formation. The end results were apparently perfect. This boy was last seen jumping and running and there was no evidence of a limp.

CASE 3—A white boy, aged 19, was injured by the explosion of a small compressed air tank, which struck him on the knee. He was immediately removed to a hospital, where an examination revealed the fact that there was a fracture of the lower shaft of the femur. There was no compounding of the fracture. A roentgenogram revealed an avulsion fracture of the lower femoral epiphysis with posterior displacement of the epiphysis. Two unsuccessful attempts at reduction were made under anesthesia. Several days later there were signs of gangrene in the foot and leg and amputation through the mid thigh was done. Following the amputation the stump healed nicely and the patient left the hospital in good condition.

SYMPTOMS

The symptoms are ordinarily those of a fracture in the region of the lower end of the femur or knee joint, an abnormal bulging appears in the popliteal space if the epiphysis is displaced posteriorly, or an anterior prominence in anterior displacement may be seen. Shock is also usually present. Palpation may reveal the true condition. However, the roentgenogram should always be taken both as a confirmatory diagnostic and as a protective measure. The treatment consists of reduction and complete immobilization for about four weeks, after which gradual motion may be established. Closed reduction should always be attempted under complete ether or local or spinal anesthesia, since complete relaxation is imperative. For reducing posterior displacements, the knee should be forcibly flexed at less than a right angle (from 75 to 80 degrees) and in this position forcible traction is made on the leg, an assistant making countertraction on the thigh, at the same time the operator manipulates the displaced epiphysis with his free hand.

Reduction having been accomplished, a plaster-of-paris cast is applied from the foot to the groin, holding the knee in strong flexion, at least 90 degrees. This position serves to lock the epiphysis and to prevent its redisplacement. A roentgenogram through the cast should be made, and if the reduction is not satisfactory the cast should be removed and another attempt at reduction made. If the epiphysis is displaced anteriorly, reduction should be attempted with the knee in full extension, and if reduction is not obtained the knee should be gently flexed during the process of extension and counterextension. After reduction, the plaster cast should hold the knee in moderate flexion. In other words, one would institute practically the same treatment as in a supracondylar fracture of the femur. Occasionally, nail extension may be indicated, especially in the compound cases. Should closed reduction be impossible, then open operation is indicated. The epiphysis is best exposed through an adequate incision along the inner or outer side of the lower thigh, or through both an inner and outer lateral incision. Should there be a laceration of tissues with a compounding of the fracture, the appropriate treatment for such an injury is indicated. In those unusually severe cases in which the large vessels have been torn, amputation may become necessary. In this connection I wish to call attention to the intracutaneous injection of physiologic solution of sodium chloride as a diagnostic measure to ascertain patency of the main vessels.

The prognosis after proper reduction is usually very good, function gradually returning to normal.

SUMMARY

- 1 Slipped lower femoral epiphysis is a rare type of injury.
- 2 Considerable force is necessary to produce this type of displacement.
- 3 This injury can occur up to the twentieth year because of the late union of the epiphysis to the shaft of the femur.
- 4 Closed reduction should be attempted only to be superseded by open operation if the former is unsuccessful.
- 5 The intracutaneous test with physiologic solution of sodium chloride should be used when one is in doubt as to the continuity of the popliteal vessels.
- 6 The prognosis is usually very favorable.

1021 Prospect Avenue

ABSTRACT OF DISCUSSION

DR M L KLINEFELTER, St Louis I agree with Dr Kurlander that this condition is relatively rare as compared with the slipping of the upper femoral epiphysis and also that in no instance have I seen a case that was not purely traumatic rather than partially due to predisposition, as in the upper femoral epiphysis. He has called attention to the seriousness of this lesion. In the first place the soft structures are severely damaged in a complete separation of the lower femoral epiphysis. I have not seen a case in which either the peroneal or both peroneal and posterior tibial nerves were paralyzed. I have seen some cases in which the vessels were absolutely occluded, in which the leg became cold and the foot became cold and dark, and in some cases practically black. The very nature of the angle on this bone is an important factor in these cases—the fact that it is an epiphyseal separation rather than a fracture makes these vessels and nerves less likely to be cut. I have reduced some cases in which the foot had been

Fig 2 (case 1)—Appearance after reduction

cold for days according to the history and certainly for a number of hours according to accurate history and the circulation was restored. The nerves have recovered in every instance in the cases in which I have had experience even though they had been out for some time. The most important point aside from the actual injury is for the general practitioner to recognize the seriousness of the lesion early. It practically always results in a paralysis and if displacement continues for any great length of time must frequently result in an amputation. I have never seen a recent case. All the cases have been brought to me as a result of complications. I have had three out of twelve in which the growth of the lower femoral epiphysis was arrested—two of these cases were not recognized and in the other one the physician told me he was unable to control the child. So I feel this might have an important bearing on the arrest of growth. The other nine were immobilized. I have been able to reduce only one by the closed method. I am struck with the extreme severity of the injury when I open the capsule which I have always had to do. In the second place a surgeon who has not the broadest knowledge available is not equipped to reduce slipped epiphyses.

after they have been off a week or more and regardless of the time they frequently cannot be reduced without damage to the epiphyseal lines and one has to use a skid with some one handle the leg and then press on the epiphysis with gauze to effect reduction without actually crushing certain parts, even when they have been off for only a week.

DR JOHN J. MOORHEAD, New York. My experience with what for want of a better name can be called a fracture dislocation of the epiphysis of the lower end of the femur is limited to two cases. Both were late cases and numerous attempts had been made under the closed method of reduction. Rather than resort to an open operation, the hazards of which have been mentioned, I inserted a transfexion pin in the upper end of the tibia and made a satisfactory reduction by traction, starting with a large poundage, 40 pounds (18 kg.) and gradually reducing it. In one of these cases the ultimate result was quite satisfactory in the other, an epiphysitis developed interfering with the growth of the limb. One of the earliest things that should be done is an immediate aspiration of the

Fig 3 (case 2) —Condition before reduction. Note callus formation.

knee joint, which relieves the tension and makes it easier to make the reduction. In the early cases in the majority of cases reduction can be made by manipulation under anesthesia. In the older cases, in which too diligent attempts have been made to reduce by the closed method and have failed, one should choose as the second choice skeletal traction. My experience is that the automobile is the big factor and the majority of the cases I have seen have occurred as a result of the legs being caught in a revolving wheel. Before the time of the automobile I think that the typical way was in hitching on a wagon and having the foot caught in the revolving wheel, particularly of a large ice wagon. As to open operation I have had no experience with it. It should be reserved for the type of case in which closed manipulation or the skeletal traction has failed.

DR R. WALLACE BILLINGTON, Nashville, Tenn. This is perhaps not quite so infrequent an accident as Dr Kurlander would have one believe. As the last speaker has just said it was known formerly as the cartwheel fracture, caused as he described it. I had the misfortune to have a bilateral case in a boy, aged 11 years, caused by an automobile accident four

weeks prior to the time I saw him. It was of the type which the two lower femoral epiphyses were separated completely and displaced anteriorly, and union had taken place the time I saw him. I thought it might be possible to reduce this under an anesthetic, although I had little hope of it. Prepared for the operation, and after feeling the condition of the limbs under anesthesia, I found them quite solid, so I proceeded to operate. The method already described was used. Lateral incisions and skidding gently, that is, by using a bone skid and making as little trauma as possible to the epiphyseal cartilages, I skidded the epiphyses back into place. It was necessary to keep the knees flexed at a right angle or a little beyond to prevent easy redislocation. The limbs were put in plaster casts in a position slightly less than 90 degrees. The operation was done four years ago, and I have not been able to get this patient up to see me recently, but I have had word from the father and from the local physician that the boy is a strong, normal boy now with no interference with the growth of either limb. The limbs are straight with no deformity; motion is unlimited. This case was not compound. There was little interference with the circulation at the time I saw him and no paralysis. I feel that I was fortunate and had a bit of good luck in getting that sort of result in a case of this kind. It is the only case of bilateral dislocation of which I have been able to learn.

DR H. W. MEYERDING, Rochester, Minn. I am greatly interested in the report of Dr Kurlander. It has been my experience that this fracture or slipped epiphysis, common results from being caught in a wheel and twisted. Occasionally one sees if early roentgenograms are taken a strip of fracture of the lower anterior border of the diaphysis. Should one have the good fortune to see the patients early immediate aspiration followed by a period of three or four to five days rest would be indicated. I have divided the fractures into two groups: first, those partially dislocated; second, those completely dislocated with or without fracture. My experience has been with those cases of long duration which have been completely dislocated anteriorly and which have gone on to fusion. At the meeting of this section a year ago I reported a series of 128 cases of Volkmann's ischemic contracture. At the time I studied these I was impressed with the similarity between that group and this group. I was impressed with the fact that although there is an impaired circulation the fractured and slipped epiphyses it does not ordinarily develop. Thus in both one finds the epitrochlear space and the popliteal space filled with blood and the upper fragment shoved downward and backward causing pressure on the blood vessels and nerves. The reduction of the fracture and the emptying of this blood clot are usually followed with improvement of the extremity. In my cases of long standing in which malunion has occurred I have found the split patella incision useful. I reduce the epiphysis with a bone skid at times I have found it necessary to maintain reduction by the use of a bone screw, following this, plaster-of-paris casts are applied.

DR PHILIP D. WILSON, Boston. In this period when it is difficult to know what every other physician is talking about anyhow, one ought to be awfully careful of the terms and think I am justified in criticizing the title under which this is presented which is 'slipping epiphysis'. I think what we are discussing is the usual traumatic separation, complete or incomplete. In the fracture service at the Massachusetts General Hospital during the last year, nine of these cases were traced over a period of five years from the time of injury and out of these nine six, or two thirds, showed complete arrest of growth. This was a striking finding and I was impressed with the fact that the shortening occurred so gradually that unless these cases were followed over a period of a long time one would not get the end-result with the total shortening. The total shortening in most of the cases was 2 or 2½ inches. In one case part fracture and part separation a portion of the epiphysis separated and stopped growing and the other portion where it had fractured higher in the bone continued to grow so a tremendous knock-kneed deformity resulted and that boy has since had to come in for an osteotomy. I was impressed with the gravity of this injury and

the necessity of warning parents when it occurred that this result might be expected. It is a result that I am confident comes from the nature of the injury itself and not from the kind of treatment. All of the cases I described were reduced by closed reduction except one which was an open reduction but one in which very good reposition had been obtained.

DR ROLAND HAMMOND, Providence, R. I. The paper and discussion so far have indicated that the author and speakers favor approximately the right angle position or at least one of flexion. I should like to point out that that position is sometimes a dangerous one. Two or three years ago I had a fresh case of this condition in which, after manipulation, I applied a plaster cast in approximately a right angle position and a subsequent roentgenogram showed a perfect reduction. I did not check the roentgenogram until about four weeks afterward and was surprised to find that the epiphysis had slipped back into its original dislocation. Since then I have had several of these and after reducing by manipulation, I have put the leg straight in complete extension and have never had any relapse. It seems to me that is the more rational position because the muscles are in a neutral position.

Fig. 4 (case 2)—Appearance after reduction showing degree of flexion necessary to hold fragments reduced.

DR J. J. KURIANDER, Cleveland. These injuries are extremely serious and I have heard several of the men in the discussion say that the shortening has been as great as 2 or 2½ inches. At the age of 19 there would be no appreciable shortening because the epiphysis is almost fully united to the shaft of the femur. The two other cases have occurred in patients within the past year and at this time I have no way of estimating what the future shortening if any will be. The children run, jump and play as normal children would. Dr. Moorhead has said that he does not use much force in the reduction and if he cannot obtain reduction he inserts a pin through the condyles and treats the condition as he would a supracondylar fracture. That is what I said in my paper, namely, that these cases would require practically the same treatment as a supracondylar fracture of the femur. But if real extension is used, considerable weight will have to be applied to obtain reduction. Dr. Wilson objected to my calling these cases "slipped epiphysis." He is probably correct as the first two cases were avulsion fractures in which, as in the first case, there is a true slipping. Dr. Hammond said he believes

that the relaxation of all the muscles is best secured when the leg is put out straight, and for that reason he advocates that position in holding the reduction. I have had only three cases, in two of which reduction was done and in the other amputation performed and I would consider this fracture analogous to a Colles fracture. One may get perfect results with a Colles fracture reduced and held straight, but a little more certain if the wrist is strongly flexed and the fragments locked and I am afraid that I shall still continue to use the extreme flexion in holding a reduced slipped lower femoral epiphysis.

NONTRAUMATIC DISLOCATIONS OF THE ATLANTO-AXIAL JOINT*

E. I. BERKHEISER, M.D.

AND

FERDINAND SEIDLER, M.D.

CHICAGO

Recently we have observed several cases of dislocation of the atlanto-axial articulation which were not associated with trauma but resulted as a complication of acute infectious diseases.

With the development of the roentgen ray, cases of traumatic dislocation of this joint have been diagnosed more frequently. Several of the cases, which have been described in the literature, had no evidence of injury to the spinal cord, but most of them were associated with fractures. The injury together with its mechanism of production and the roentgenographic appearances have been thoroughly described in the literature.

Many cases of dislocation have been noted which are the result of destructive diseases, such as tuberculosis and syphilis, but we were unable to find any reported cases of simple dislocation without associated trauma or destruction of bone.

The cases included in this report were dislocations at the atlanto-axial articulation which were direct complications of upper respiratory infections.

ANATOMY

For a proper understanding of this condition the normal anatomy of this region must be considered.

The atlas-axial articulation is complicated in that it is made up of four distinct joints, which permit a wide rotation of the atlas on the axis. These are the atlanto-odontoid joint of Cruveilhier, which is a pivot articulation between the odontoid process of the axis and the posterior surface of the anterior arch of the atlas, the syndesmo-odontoid joint which is a sliding joint between the posterior surface of the odontoid process and the anterior surface of the transverse ligament and the two gliding joints between the lateral masses on each side.

The articulating facets between the atlas and the axis are almost plane. The inferior facets of the atlas are almost circular, while the superior facets of the axis are more oval. The plane of the facets of the axis is of the most importance in that it is inclined downward from its posterior margin, both anteriorly and laterally. The joint capsules are loose, permitting a wide range of motion.

The ligamentous structures connecting these two vertebrae consist of the anterior and posterior atlanto-axial ligaments which are continuous with the anterior

*Owing to lack of space, several illustrations have been omitted. The complete article appears in the author's reprint.

*Read before the Section on Orthopedic Surgery at the Eighty-Eighth Annual Session of the American Medical Association, Detroit, June 1, 1916.

and posterior spinal ligaments. The latter is reinforced by a membrane, which attaches the anterior rim of the foramen magnum to the axis.

The ligamentum transversum atlantis, which is the horizontal portion of the cruciform ligament, is one of the strongest ligaments. It is attached to the lateral masses of the atlas posterior to the odontoid process and is separated from it by a bursa.

The normal relationship of these vertebrae to each other, forming the neural canal, depends on the ligaments, and any loss of the ligamentous supports either by rupture or relaxation will result in dislocation and danger of subsequent compression of the spinal cord. Also in the forward dislocation of the atlas on the axis there may be an injury to the vertebral arteries as they pass through the foramina in the lateral processes of the atlas.

ROENTGENOGRAPHIC CONSIDERATIONS

This lesion can be demonstrated best by projections of the craniocervical region with the patient lying on his side. Stereoscopic views of the bones and joints of this region are better than the anteroposterior and the lateral views.

The patient's head should be placed so that its sagittal plane is parallel to the plane of the film, thus bringing it in direct line with the long axis of the spine, with the weight of the body resting on the shoulder. This can

FIG. 1.—A, normal relation of the atlas and axis. B, overlapping anterior articular surfaces in unilateral dislocations of the atlas on the axis.

be best accomplished by the use of a hard pillow or a block of proper thickness on which the film is laid.

The anteroposterior view is of value in this type of dislocation, especially for the demonstration of lateral displacement of the involved bones and the overlapping of the articular surfaces. This view is difficult for the roentgenologist to obtain, because on the direct anteroposterior projection the atlas and a part of the axis are covered by the shadows of the occipital or those of the mandible, or both. Hence, the view of the atlas-axial region is frequently interpreted as negative because one is not able to see these structures.

The patient should be placed in a supine position, the mouth opened as wide as possible and maintained by a cork or other roentgen transparent material placed between the teeth.

The central axis of the roentgen ray is passed through the center of the mouth, emerging just below the occiput. The result will be a clear shadow of the atlas, the odontoid process and the body of the axis.

The lateral view of the normal structures reveals the shadow of the anterior arch of the atlas in close apposition to the odontoid process.

The foramen magnum is exactly over the space behind the shadow of the odontoid process and anterior to the shadow of the posterior arch of the atlas. All the cervical bodies are in line with one another, being so arranged as to form a continuous curve with its convexity forward. A line drawn on the roentgen film from

the anterior edge of the atlas will connect all the anterior margins of the cervical vertebrae in a continuous arc, while a similar line, if drawn from the posterior surface of the odontoid process downward, will describe an arc touching the posterior surfaces of the bodies of the cervical vertebrae and will represent the anterior margin of the spinal canal.

The shadow of the angle of the mandible is close to the anterior edge of the cervical bodies when the head is held in the normal position. The anteroposterior view will show an even spacing of the two lateral masses of the atlas with the odontoid process between them and the joint spaces between the articulations of the atlas and the axis will be symmetrical and clearly visible.

ROENTGEN APPEARANCE IN THE DISLOCATION

In dislocations of the atlanto-axial joint these relations are disturbed according to the degree of forward or backward luxation and according to whether it is unilateral or bilateral.

In the anterior dislocation, the lateral view shows the anterior arch of the atlas relatively farther forward with respect to the odontoid. The lateral mass of the atlas and the spinous process of the axis do not converge but are divergent, so that the posterior arch of the atlas approximates the occiput more closely than normal, which shows that the atlas is tilted downward and forward on the axis.

In unilateral dislocations the atlas is tilted to one side, and hence the posterior arch appears broader than normal.

The shadow of the lateral masses are both visible, so that one is able to see the neural canal.

In the anteroposterior views the odontoid process of the axis is not seen in its normal relation to the atlas. The absence of the joint space between the lateral facets of the atlas and axis is pathognomonic of this condition.

There is either a complete overlapping or a diminution of the joint space on one or on both sides, depending on the type of dislocation.

In the unilateral type, where there is an overlapping only on one side, the opposite joint space is abnormally wide.

MECHANISM OF PRODUCTION

It is generally known and accepted that a large effusion into a joint, as the result of an inflammatory process, is frequently associated with considerable relaxation of the joint capsule and ligaments resulting in a pathologic dislocation.

Every one is familiar with the pathologic dislocation of the hip without bone destruction. It is logical to assume that a similar process could occur in the atlanto-axial articulations, which are mechanically weak because of the position of the articulating facets and large loose joint capsules.

The same process may take place in the anterior and posterior bursae, which separate the odontoid process from the atlas and the transverse ligament, respectively. The localization in the posterior bursa would naturally involve and weaken the transverse ligament, which is normally stronger than the odontoid process, and, hence, in traumatic conditions the process is fractured before the ligament is ruptured. With the relaxation of these structures and with the mechanical weakness of these joints, it is easily understood how these joints acquire a hypermobility with resulting dislocation.

There are three types of dislocation.

The slanting position of the articulating facets predispose to a forward position of the atlas either as a unilateral or a bilateral dislocation.

A bilateral posterior dislocation is impossible because of the approximation of the odontoid process to the posterior surface of the anterior arch of the atlas, but there may be a unilateral posterior dislocation. A further reason why the anterior type predominates may be explained by the fact that the center of gravity of

the head is farther forward than the anatomic support. Any other factors producing flexion of the head on the neck, such as recumbency with pillows under the head, will also predispose to the forward dislocation.

ETIOLOGIC FACTORS

All of the patients had an upper respiratory infection, which preceded the symptoms in the neck from a few days to two weeks. Patient 1 developed an arthritis in other joints and a pericarditis before the neck involvement. Patient 2 had scarlet fever and a throat infection,

which was thought to have been diphtheria, but this was not proved by cultures. Patient 3 had a definite acute conjunctivitis. Patient 4 had a cold and tonsillitis, while patient 5 had a definite acute attack of influenza.

From the foregoing histories it is evident that there was a definite relationship between the previous infection and the disability of the neck, and since it happened in five cases it cannot be spoken of as accidental but rather as a definite etiologic factor.

Since none of these patients were seen by us during the original acute illness, it was not possible to determine the exact type of infection, although the streptococcus seemed the most probable.

The infection may become located in these articulations either through the blood stream or by way of the lymphatics, since there is a direct connection of the drainage from the pharynx and the upper cervical spine through the retropharyngeal glands, and these with the deep cervical glands, which were palpable in cases 2 and 3.

SYMPTOMS

The striking feature presented in all these cases was the torticollis without evidence of nerve injury except for the peripheral nerve irritation.

There was a few degrees of motion in flexion and extension. Rotation in the direction increasing the deformity was slight but none was possible toward the midline. Any passive attempts at correction of the deformity—even the slightest jarring of the head—elicited severe pain.

On palpation the spinous process of the second cervical vertebra was very prominent and it deviated toward the side to which the chin pointed. In an attempt to correct the deformity, the deviation increased, while in an attempt to exaggerate the deformity it approximated the midline.

Because the atlas and the axis are locked in the dislocation, no rotation of the atlas on the axis is possible.

The patient, in attempting to correct the position, moves the axis together with the lower cervical spine in the opposite direction. Therefore, in increasing the real pathologic rotation, the compensatory motion in the opposite direction is no longer present and the spinous process is found in the midline. This phenomenon was described by Sudeck, in a report of two cases of atlanto-axial dislocation.

In a bilateral dislocation, one is able to palpate the lateral bony masses in either side of the neck just posterior to the angle of the mandible.

In unilateral anterior dislocation, the rotation of the chin is away from the dislocated side.

It is a rotation dislocation with the odontoid process serving as an axis up to a certain degree of rotation. This symmetrical dislocation is stopped as soon as the posterior movement of the opposite process cannot go farther, and hence it serves as a fixed point and this now becomes the axis. As the rotation is then continued, the articulating surface of the atlas moves farther forward, so that there is no apposition with the articulating surface of the axis. This results in the locking of the bones and the fixation of the dislocation.

In the unilateral posterior dislocation the rotation is toward the dislocated side and the articulating surfaces on the opposite side are separated from each other a little farther than normal.

TREATMENT

The treatment naturally consists of the reduction of the dislocation. This may be accomplished (1) by constant traction, or (2) by forcible manipulation under anesthesia. Four cases were treated by traction and one by manipulation.

Traction is best accomplished by placing the patient on a Bradford frame for a few days. During this time the patients become accustomed

to the position. It was remarkable how comfortable the patients became in a short time although two patients previously refused to lie down and were propped up in bed in a sitting position. As soon as the patient was comfortable, a slight constant traction was applied by means of a head halter and weight over a pulley at the head of the bed. The traction was applied in a longi-

Fig. 2 (case 1)—Lateral view showing forward displacement of the head and atlas on the axis and other cervicals. Note the position of the odontoid process near the posterior arch of the atlas.

Fig. 4 (case 1)—Lateral view after reduction. Note now the normal relations between the axis and the atlas.

tudinal direction at first. With relief of the muscle spasm, the traction was increased, and the direction of the traction was altered so as to obtain hyperextension of the head and the neck.

The hyperextension was obtained by placing a rolled sheet transversely under the neck and by bending the side bars of the frame at the level of the lower cervical spine.

It should be emphasized that the important features of the treatment are the constancy of the traction, the fixation of the body to the Bradford frame, which immobilizes the entire spine and the hyperextension.

In the course of a few days a definite improvement of the position was noted with an increased range of motion. The progress of the reduction and the course of the treatment as to the length of time of recumbency and the amount and direction of the traction was directed by physical examination and roentgenograms. The time necessary for the reduction varied from eight days to five months.

Case 1, which required five months for reduction, was bilateral and the most severe type observed. Because of the poor general condition of the patient—especially her cardiac condition—extreme care was necessary. As

Fig. 6 (case 3)—View through open mouth again showing dissimilarity at lateral joints between the atlas and the axis. Overlap of articulating facets on the right side.

this was our first case to be treated in this manner we did not force the treatment, and, hence, more time was necessary.

The duration of the dislocation did not seem to influence the length of time necessary for the reduction.

After the reduction was accomplished the traction was continued for a variable length of time, and then a plaster cast was applied, extending from the occiput and chin down to the lower ribs. In a few days the patients were permitted to sit up and soon afterward they were ambulatory. After a few weeks' time only a plaster collar was applied, which gave more freedom of motion. When this collar was removed, a cotton roll collar was applied for protection and active motions were encouraged.

Patient 5 was treated by forcible manipulation under anesthesia, because the parents did not wish to have the patient hospitalized for a prolonged period of time.

Under complete anesthesia with muscle relaxation the deformity persisted. In the manipulation moderate traction was applied to the head, increasing the tilt of the head to the right and rotation to the left. From this position the head was slowly rotated to the right and tilted to the left. While this procedure was being accomplished there was a definite snap, which was felt

and heard. After this, the head and neck assumed the normal position and the head was freely movable on the neck in all directions. A plaster cast was applied to the head, neck and thorax with the position overcorrected, i. e., with the head rotated to the right and tilted to the left.

Although the reduction immediately after this procedure was satisfactory, it was shown in the later course that traction could not be dispensed with.

The forcible manipulation reduced the deformity, but the plaster-of-paris cast maintained the compensatory rotation in the lower cervical spine, where, as in the traction method, both the original and the compensatory rotations were corrected simultaneously.

CONCLUSIONS

1 In five cases of nontraumatic dislocation of the atlanto-axial joint, occurring in children from 8 to 11 years of age one was a bilateral forward dislocation while four were unilateral—two anterior and two posterior.

2 These occurred as a complication from one to two weeks after an acute upper respiratory infection.

3 They presented a rather characteristic torticollis deformity, with marked fixation and pain on attempted motion.

4 Roentgenograms showing this dislocation are difficult to obtain when the extreme deformity is present, and hence, they are usually interpreted as negative. But when a good view of this region is seen, the dislocation is shown in an overlap of the lateral articulating facets. As the dislocation is further reduced, the overlap diminishes and the joint space reappears.

In the unilateral anterior dislocation the chin deviates to the opposite side, while in the posterior dislocation the chin deviates toward the same side.

The lateral view in the anterior dislocation shows the anterior arch of the atlas to be misplaced relatively far forward with respect to the odontoid.

5 All these dislocations were reduced—four by means of constant traction in hyperextension and the other case by forcible manipulation under anesthesia.

REPORT OF CASES

CASE 1—H. K., a girl aged 8 years was admitted to the hospital Nov. 26, 1928, because of swelling, stiffness of the neck and inability to open her mouth. Three months before she had had a swelling of her fingers and of her right foot. At times the symptoms were worse in the fingers and at other times they were worse in the foot. One month later the neck became tender and swollen in the back. She was unable to open her mouth because of pain. She could walk about with care and sit but she refused to lie down because recumbency aggravated the pain in the neck. There was headache and general weakness with the loss of 10 pounds (4.5 kg.) in weight. She was sent to the hospital with a diagnosis of cervical Pott's disease.

The family history was negative for tuberculosis.

When first seen the swelling of the fingers and of the foot was no longer present and there was free motion in all the joints. She was able to walk but took her steps with extreme care so as to avoid any jarring of the head and neck, which she supported with both hands. She sat down with extreme care. The neck seemed short. The head was held forward and rotated to the right with a slight tilting to the left. There was no active motion in any direction. Any attempt at passive motion elicited great pain. A marked bony prominence could be felt posteriorly to the right of the midline which was the spinous process of the second cervical vertebra or axis. The transverse processes of the atlas could be felt on both sides of the neck, more distinctly on the right side just above the

angle of the jaw. There was no evidence of spinal cord or sympathetic nerve involvement in that all the reflexes were present and normal and the pupils were equal and reacted to light and in accommodation. The only nervous symptoms were the subjective ones of neuralgia and pain in the head. There was no swelling in the fingers or foot and all motions were normal. The examination of the chest and abdomen was negative, except for the cardiac condition which consisted of enlargement to the left with a systolic murmur over the apex, which was transmitted to the left.

Laboratory observations showed a slight anemia in the blood picture with a normal white blood cell count.

The urine was normal and the Pirquet and Wassermann reactions were negative.

The lateral roentgenogram of the upper cervical vertebrae, taken November 28, revealed a marked forward dislocation of the atlas on the axis. It was tilted so that the anterior process lay anterior to the body of the axis. The distance between the posterior process of the atlas and the spinous process of the axis was greatly increased. In fact it was displaced upward and forward so that it appeared to be in contact with the occiput. Furthermore, it approximated the odontoid process so closely that it was difficult to understand or conceive where there was space sufficient for the spinal cord. The atlas was not dislocated directly anterior but was also tilted to the right, so that one was able to see through the neural canal.

The anteroposterior view taken the same date through the open mouth presented difficulties of analysis. The most striking feature was the appearance of a circular opening on the bony ring that lies directly over the vertebral column and was interpreted as the neural canal of the axis. The lateral articulations of the atlanto-axial joint could not be made out because the vertebrae overlapped each other, obscuring them and the odontoid process was displaced from its normal position. The right lateral process of the atlas was displaced farther toward the right and in it the transverse foramen could be seen.

December 6 the patient was placed on a Bradford frame, and two days later extension was applied by means of a head halter with weight and pulley traction, which gave immediate relief. In ten days there was less rigidity and the neck was much straighter. One week later the patient could open her mouth much wider, and her head was in good position.

Roentgenograms taken Jan. 2, 1929 (fig. 2) still showed a marked forward displacement of the atlas with some tilting both forward and to one side on the axis. The posterior process of the atlas was not as close to the occiput because the vertebra was not tilted as far as it was at first. This diminution of the tilt was also shown in that the anterior process did not extend downward anterior to the axis as far as in earlier views. The odontoid process was seen plainly in its normal position and there was no evidence of any pathologic changes. The rather marked compensatory lordosis seen in early views was considerably diminished. The anteroposterior view (fig. 3) also showed a diminution of the tilt of the atlas on the axis as the bony ring was now seen to be more oval and not circular as it had appeared originally. The joint spaces of the lateral articulations between the atlas and the axis could not be seen, but one could see the articular processes, which overlapped each other on both sides.

The amount of the constant traction was increased with greater hyperextension and the accompanying roentgenograms were obtained May 6. The lateral view (fig. 4) showed the atlas in normal relation to the axis and the anteroposterior view (fig. 5) showed the normal joint spaces of the lateral articulations between the atlas and the axis. The transverse processes of the atlas were symmetrically placed with respect to the odontoid and the transverse foramina could not be seen.

September 25 the patient could open her mouth the natural width the position of head and neck was normal and there was no restriction of motion. Traction was removed and a plaster cast was applied from the chin and occiput down to the crest of the ilium.

November 2 she was discharged from the hospital wearing the plaster collar. She could walk and sit without discomfort.

December 30 the cast was removed. There was no deformity of the head or neck but there was some restriction of motion in all directions. Feb. 10, 1930 there was limitation of motion

to the left, but actively she could rotate the head to the right about 45 degrees. Lateral bending, flexion and extension were almost free. The spinous process of the axis was still more prominent than is normal, although it was in the midline.

Roentgenograms, February 10, showed in the lateral view that the atlas was farther forward on the axis than it was in the previous roentgenogram and there was an increase of the cervical lordosis. The anteroposterior view revealed a decided narrowing of the joint space of the left atlanto-axial articulation. As these observations indicated a recurring dislocation of the atlas on the axis a leather collar was made and applied to maintain hyperextension.

CASE 2—C. A., a girl, aged 10 years, was admitted to the hospital, Aug. 13, 1929, because of a crooked neck, which was painful on attempted motion. Four months before she had had scarlet fever and diphtheria (?). The second day she had received an injection in the buttock and two days later was unable to move her legs. Then, the following day she could not move her arms and the next day she was unable to move her neck. Four days later she regained the use of her arms and legs. However, she did not regain normal motion of her neck, although the pain disappeared after two months. There was no swelling of the neck at any time. The rest of the personal and family history was irrelevant.

The child was undernourished but was otherwise normal except for the deformity of the head and neck. The head was

Fig. 7 (case 3)—Appearance one month later after clinical cure. The two joints are now similar.

turned to the right with the neck flexed so as to depress the chin on the chest. The head was tilted slightly to the left. Actively she was able to rotate the head a few degrees more to the right but there was no active rotation to the left and passive attempts caused pain. There was only a few degrees of flexion or extension. All reflexes were normal.

Laboratory observations including the Wassermann and Pirquet reactions were negative. A roentgenogram taken August 12 through the open mouth showed in the anteroposterior view an overlapping of the articular surfaces of the atlas and the axis on the left side while on the right side they did not overlap and the normal joint space could be readily seen. The position of the mandible indicated a tilt of the head to the left with rotation of the head to the right. There was a compensatory rotation below the second cervical vertebra to the left, as was shown by the position of the transverse processes.

The lateral view taken on the same date showed the atlas a little farther forward on the axis than is normal.

August 14 the patient was placed on a Bradford frame with extension by means of a head halter, weight and pulley traction. She was comfortable immediately. After eight days treatment in this manner roentgenograms were taken which showed the head in normal position. The left atlanto-axial articulation which could not be seen in the previous view was now plainly visible although the joint space was not as wide as it was on the opposite side.

September 17 the deformity was well corrected and there was free motion within almost the normal limits in all directions.

September 18 the traction was removed and a plaster collar was applied. September 29 the patient was discharged from the hospital, wearing the plaster collar.

CASE 3—J. P., a boy aged 9 years entered the Presbyterian Hospital in the pediatric service of Dr. Grulee Oct. 6, 1929, with the complaint of a stiff neck and fever.

He had caught cold in the head three weeks before admission. About two weeks later he began to complain of the stiffness of the neck and of pain on motion. He was taken to a

Fig. 8 (case 4)—Original deformity.

hospital and discharged after three days with a diagnosis of neuralgia of the neck and tic douloureux. The pain became so severe that he was unable to move his head or permit the least jarring. In fact, he was exhausted from holding his body tense. He was suffering with a sore throat and fever during this time. He was always conscious and had no symptoms of meningeal irritation. His past history was negative except for frequent sore throats and a tonsillectomy four years before.

The patient was well developed and well nourished. He lay in bed with his head rotated to the right

almost 90 degrees. There was a marked involuntary muscle spasm and the left sternocleidomastoid muscle was very tense. There was bilateral cervical adenitis, but the glands were not tender to palpation. The spinous process of the second cervical vertebra was very prominent posteriorly and to the right of the midline.

There was no active motion and any attempts at passive motion elicited extreme pain. There were no other abnormal physical observations, except for evidence of sore throat which consisted of a red granular appearance of the tonsillar pillars and pharynx.

Roentgenograms were taken on admission to the hospital. Figure 6 showed a condition similar to that in case 2 in that there was an overlapping of the lateral articulations between the atlas and axis on the right side and an increase of the joint space on the left. But it must be noticed that in this case the head was rotated toward the dislocated side, which indicated a posterior subluxation.

October 10, he was placed on a Bradford frame and traction was applied. After one week of treatment he did not complain of pain and could move his head through an arc of about 30 degrees. The traction was then increased and one week later he was able to rotate the head actively 30 degrees to the left of the midline.

Roentgenograms taken, October 25 (fig. 7), showed both joints to be symmetrical. December 5, the traction was removed and a plaster collar applied. December 15 he was ambulatory without any discomfort. December 22, when the plaster collar was changed there was normal position of the head and free motion in all directions. Another plaster collar was applied for protection, and he was discharged from the hospital, December 24. Two months later the collar was removed.

CASE 4—N. D., a boy aged 11 years entered the hospital Sept. 9, 1929, complaining of a stiff and painful neck of two months' duration.

He had contracted a cold and a sore throat two months previously while watching an airplane take off, and two days later he complained of stiffness and pain in his neck. The pain became gradually worse so that the least jarring was unbearable. There was a feeling of soreness in the mandible. There

was no history of injury or previous attacks of similar trouble. The family and previous history was irrelevant.

The boy was well nourished and well developed. He did not appear to be ill. His head and neck were shifted to the right. His chin pointed to the right with some tilt of the head to the left and slightly forward.

There was a right convex cervical scoliosis with a compensatory scoliosis to the left in the upper dorsal region. There was very little motion present. Actively, he could rotate the head a little farther to the right but not to the left. There was a little motion in flexion but no extension. Attempts to move the head passively on the neck caused much pain. When attempting to lie down, he first lay on his abdomen and while supporting his head with both hands rolled over on his back, which was a less painful procedure than to lie down naturally. Except for the foregoing observations, the physical examination was negative, as were the laboratory observations including the blood examination and the Pirquet and the Wassermann reactions.

Roentgenograms showing the condition of the atlanto-axial region at the time of admission could not be obtained because of the deformity and the patient's inability to open his mouth wide enough. He was placed on a Bradford frame with traction on the head. October 11, the position of the head was much improved.

Roentgenograms taken at this time showed in the lateral view the atlas tilted on the axis so that the shadow was oblique and thrown on the occiput. The anterior view (fig. 9 A) aided greatly in recognizing the displacement, which was the same as in figure 6.

After further treatment with traction and greater hyperextension roentgenograms taken November 13 showed normal relations of the atlas and the axis (fig. 9 B). The traction was removed and a plaster cast applied Jan. 8, 1930, when the cast was changed there was free range of motion of the head and neck and he was discharged January 10 wearing this collar. February 3 the plaster collar was replaced by a roll collar of cotton and bandage.

CASE 5—E. C., a girl aged 9 years was sent to one of us (F. C. S.), June 19, 1929, for the correction of a deformity of the head and neck, which had been previously diagnosed as an hysterical torticollis.

Her past history revealed that she had had an acute attack of influenza, Christmas, 1928. One week later she developed a torticollis which had persisted. There was no history of trauma or other illness.

On examination she presented the appearance of a rather anemic, undernourished child. The head was tilted extremely to the right and rotated to the left. There was a marked right cervical scoliosis in the lower cervical region, which gave the impression

Fig. 10 (case 4)—After reduction of the dislocation.

that the head and upper portion of the neck were shifted to the left. The head was held fixed. There was no active or passive motion in any direction, except for a few degrees of flexion and extension. Any attempt to correct her position passively was extremely painful. The right shoulder was held elevated higher than the left.

The laboratory observations including the Pirquet and the Wassermann reactions were negative.

A roentgenogram taken through the wide open mouth (fig. 12) June 26 showed a marked rotation of the head so that

the mandible deviated to the left of the midline with some tilting of the head to the right

The lateral articulation of the atlas and axis on the right side was overlapped completely, while on the left side the joint space was visible. The right transverse process of the atlas was closely approximated to the third cervical vertebra, which demonstrated that it was completely displaced and tilted forward. The lower cervical spine showed plainly a marked compensatory rotation as the third and fourth vertebrae were seen to be projected as a lateral view instead of the antero-posterior view.

There was a right convex scoliosis in the lower cervical spine. The lateral view, taken the same day, showed the odontoid process intact and the atlas displaced forward and tilted to one side.

June 23 forcible reduction was accomplished, as described later in the treatment.

She was held in a cast for twelve weeks and careful active and passive motions were then encouraged. Since the compensatory rotation did not disappear, traction was applied for two weeks, which markedly improved her condition. Another plaster collar was applied for six weeks with the head in the normal position, and on the removal of this collar the head was in good position but rotation was still restricted.

She was left without support during the day but had slight traction applied during her sleep. When last seen, there was no deformity or restriction of motion.

A roentgenogram, May 19, 1930, showed the atlanto-axial joint spaces to be symmetrical. The scoliosis and rotation of the lower cervical spine were markedly diminished. The lateral view on the same date showed almost normal relations of the atlas to the axis. After this time the immobilization was discontinued except for slight traction during her sleep.

7 West Madison Street

ABSTRACT OF DISCUSSION

DR FRANK C MURPHY, Chicago. If this is done under forced manipulation, is there ever any possibility of catching the odontoid process forward on the cord and injuring the cord?

DR C A STONE, St Louis. I should like to ask why the authors feel it is necessary to keep traction on these patients for that period of time. I do not think that one needs to be particularly afraid that damage is to be done in manipulating these necks if a little care is taken about it, if one is not rough, as is a chiropractor, and if one will depend more on manipulation than on traction. Some necks can be retained with an ordinary Thomas collar. Some need a plaster collar to hold them in position.

DR ROBERT D SCHROCK, Omaha. These patients become so tired of the plaster collar fixation that it requires all the facilities of the physician's mind to persuade them that that thing is still a little longer necessary to wear. Owing to the fact that I was not able to persuade some individuals, particularly those with cervical spine injuries, that it was necessary to remain so for longer than twelve weeks, it became necessary to devise a simpler type of fixation and something that could be used in minor cervical injuries or for the period of less rigid fixation when the plaster collar is removed. I employ a comfortable, light, readily applied and unfortunately readily removable piece of apparatus that can be made by any mechanic. It gives a nice fixation, the basis being a sternal piece and the portion holding the head on the chin cup being simply a piece of molded metal covered with leather. It is adaptable for this later stage of the serious cervical spine injury or for the minor cervical or painful necks, the arthritic type.

DR HAROLD SWANBERG, Quincy, Ill. All of the authors cases were in children, but this condition may occur in adults. I saw an atlanto-axial dislocation in an adult which occurred during the World War. A soldier aged 22 suffered from tonsillitis and measles. A month after the tonsillitis his tonsils were removed. The evening of the operation his neck became suddenly stiff, remaining in that condition when he was sent to the general hospital where I was stationed. I first saw him six months after the onset of the stiffened neck. He then had a rigid painful neck with depressed chin and a roentgen diag-

nosis of osteoarthritis of the first and second cervical vertebrae. The only other clinical symptoms were persistent headaches. Unfortunately, the first roentgen diagnosis was incorrect, there being no evidence of osteoarthritis but of a complete anterior dislocation of the atlas. I presume it will be concluded that this dislocation was a traumatic one, occurring at the time of operation, with the operation performed under general anesthesia. The tonsils were removed under a local anesthetic. The soldier and the surgeon stated that no undue force was used. The pain and stiffness in the neck came on suddenly, the night of the operation. Unfortunately, the condition was not correctly diagnosed for six months. At that time, the patient was given a general anesthetic and suspended by his neck, and various manipulative efforts were made but the dislocation remained unchanged. Every anterior dislocated atlas that I have examined shows one clinical sign not mentioned by the authors. The posterior nasal pharynx is greatly reduced in size because of the projecting anterior arch of the atlas. By placing the finger in the mouth, one can readily palpate the large projection.

DR E J BERKHEISER, Chicago. Undoubtedly this is not a new thing, but it has not been diagnosed as often as it should have been. It is, I think, because good roentgenograms cannot be obtained with the extreme deformity and because the roentgenograms are not good that they are usually interpreted as being negative. In regard to the length of time of treatment, I feel that this is really quite variable. We may have treated them with traction longer than was necessary. Probably the necks could be held shortly after the reduction with some simple appliance.

Clinical Notes, Suggestions and New Instruments

APOPLEXY OF KIDNEY BED

ANDREW BONTHIUS, M.D., PASADENA, CALIF.

Raye, in 1839, first reported a case of spontaneous perirenal hemorrhage. Wunderlick, in 1846, who was the second to report a case, called it apoplexy of the kidney bed. There have been sixty-two cases reported since then, very few of which were correctly diagnosed preoperatively or ante mortem.

Following is the report of another case.

A woman, aged 55, 5 feet 8 inches (173 cm) tall, weighing 200 pounds (91 Kg), a widow working as a domestic up to the onset of the present illness, had enjoyed good health previous to 1923. In that year, she had had a panhysterectomy with complete recovery, and later influenza. In 1924 she had extensive burns of the arms, hands, face and dorsal surface of the trunk, and was in a hospital thirty-five days. She apparently completely recovered.

In 1925 she had a cholecystectomy and an appendectomy during convalescence albumin and granular casts were found in the urine and frequent erythrocytes and for several days she suffered excruciating pain in the suprapubic and lumbar regions. The cause of this pain was undetermined. She was in the hospital forty-eight days and completely recovered.

The present illness began Sept 4, 1929 with frequent urination that lasted only that day. September 5 while working in the kitchen she had a terrific pain in the upper left quadrant of the abdomen. She had no urinary disturbances since coming under observation. September 8 the rigidity and pain in the left rectus were sufficiently decreased to permit the palpation of a mass the size of a large orange near the posterior abdominal wall in the region of the left kidney. There was a slight rise in temperature. The blood pressure was 140 systolic and 80 diastolic, pulse 72 and respiration 18.

The mass increased in size from day to day.

On cystoscopic examination the left ureter appeared to be inflamed and the right one normal. Ureteral catheters were inserted to the pelvis. The trigon and vesical neck were inflamed, the inflammation extended to the posterior urethra. The bladder capacity was 200 cc. Phenolsulphonphthalein appeared first in the left side in five and one half minutes and

in the right side in four minutes a total of 40 per cent was eliminated in fifteen minutes.

The catheterized urine from the bladder amounted to 11 cc and contained a few erythrocytes and leucocytes. The urine collected from the right kidney and from the left kidney, each contained some erythrocytes and leucocytes.

The bilateral kidney function test was as follows. The amount in the right kidney was 5 cc, 12 per cent; the amount in the left kidney was 6 cc, 14 per cent; a total of 26 per cent.

The bladder culture gave a pure growth of *Staphylococcus albus*.

A trace of sugar was shown in two of four different urinalyses. Blood counts taken between September 7 and 20 revealed erythrocytes, from 3,500,000 to 4,440,000; leucocytes, from 8,900 to 5,300; and hemoglobin, from 70 to 47 per cent.

Films of both kidneys taken Sept. 11, 1929, without catheters in position showed that the right kidney was normal in size, shape and position but that the left was enlarged to more than double its normal size, and was nearly round. Its lower pole lay about 5 cm above the iliac crest. The roentgenologic diagnosis was enlarged left kidney.

September 19, a single anteroposterior view of the urinary tract was taken with a catheter in the left ureter and the left kidney pelvis injected with opaque material. The kidney pelvis and its calices appeared large but not distended, and the secondary calices showed fairly clear cut ends. The shadow of the kidney pelvis and its calices appeared to be in the upper half of a soft tissue mass which extended from the eleventh rib downward to slightly below the crest of the ilium measuring about 20 cm. This soft mass had been repeatedly seen on previous films. I believe it was due to a mass in close relation to the left kidney.

The size of the mass increased from day to day until by palpation it became apparently about 6 inches in diameter.

Fig 1—Left kidney shadow prior to nephrectomy

Lenk and, later, Meyer stated that the syndrome of (a) severe pain in the abdomen in the kidney region (b) internal hemorrhage and (c) evidence of tumor in the abdomen signally increasing in size are usually present in perirenal hemorrhage. A review of the accompanying blood reports robs one of any certainty that an internal hemorrhage has taken place. There were only two constant and distinct symptoms present that warranted more than a working diagnosis preoperatively: they were (a) pain in the abdomen, left side and (b) a large mass the origin of which could be determined only tentatively. The

difficulty was increased by the similarity of the chemical and microscopic examinations of the urine from the left and the right kidney.

The preoperative diagnosis made was (1) hypernephroma of the left kidney or (2) retroperitoneal tumor in the left side.

An exploratory operation was performed, September 21, by Dr W. F. Manuel. Under gas oxygen anesthesia, a curved incision was made through the skin of the left flank and down

Fig 2—Hematoma and kidney removed en masse

to the perirenal fat. Exploration revealed a smooth, firm subcutaneous tumor about the size of a large coconut, easily free from the surrounding fat, movable, but firmly attached to the kidney. It was somewhat mottled gray and granular in appearance, resembling an organized blood clot. The tumor which was easily delivered through the wound, was removed. There was little bleeding. The remaining fatty tissue approximate so as partially to fill the large cavity, and three wicks were inserted for drainage. The wound was closed in layers and the patient returned to the ward in good condition.

The wound drained freely for ten days. The drainage tube was removed October 4. The patient was up, October 11 and discharged October 13, three weeks after the operation.

A phenolsulphonphthalein test on the right kidney totaled 40 per cent, October 8.

The pathologic report by Dr R. M. Crumrine showed a specimen weighing 688 Gm, comprising a kidney which appeared normal and measured 11 by 5 by 4.5 cm. Attached at the hilus was a much larger mass measuring 17 by 9 by 6 cm, that appeared to be perirenal fat infiltrated with partly organized blood clot. The kidney hilus was attached to the mass by two or three fibrous bands. The mass itself weighed 550 Gm, was covered by a thin capsule, and had the shape of an enormous suprarenal gland. The gross appearance of this specimen suggested a hemorrhage into the suprarenal. There was no suggestion of cancer. The kidney proper showed a smooth subcapsular surface and was normal in every respect, except that there was increased fat in the pelvis and a few small cysts.

The histologic slides showed organizing blood clot intermingled with fatty tissue. There were alternate areas of fresh cells and fibrosed organized clots, indicating oozing or repeated hemorrhage for at least ten days.

Sections from the kidney proper showed it to be in good condition consistent with the age of the patient. There were only rare fibrosed glomeruli.

The walls of the arterioles were slightly thickened, but not more than would be expected at this age. There was no atheroma.

There was slight definite acute inflammatory reaction of interstitial distribution apparently invading from the hemorrhage material at the hilus and not a pyelitis.

No suprarenal gland or other structure was shown. There was no evidence of malignancy.

The diagnosis was massive slow hemorrhage into the fat about the hilus, of undetermined origin

SUMMARY

The patient was apparently entirely well at the time of the sudden onset

She had not sustained any known injury recently prior to the acute attack

The kidney function was normal

Microscopically the ureter and pelvis of the left kidney were normal

The pain in the left half of the abdomen was severe

A tumor mass was palpable in the left kidney region. It steadily increased in size for about ten days but there was no evidence of internal hemorrhage

A hematoma of the kidney bed completely enveloping the left kidney was resected *en masse*

Microscopically, the origin of the hemorrhage could not be determined and was extracapsular and into the adipose structure of the kidney bed

It was a spontaneous hemorrhage into the kidney bed

The patient now one year after the date of the operation is well and earning her livelihood

65 North Madison Avenue

COLD URTICARIA AND HISTAMINE ALLERGY: REPORT OF A CASE*

L. MINOR BLACKFORD, M.D., ATLANTA, GA.

In the last four years, Thomas Lewis and his associates have done much work on the effect of cold on the human skin. They have proved the unusually high histamine content of the normal skin (1:100,000) and have devised ingenious experiments to show that histamine or a substance like histamine is responsible for the urticarial wheals sometimes produced by cold. In one

Fig 1—Wheals ten minutes after a twenty minute bath at 20° C

of these papers¹ they reviewed the literature and assembled two small groups. In group 1 urticaria was complicated by transient hemoglobinuria and syphilis was usually present. The first case was reported in 1879. Hemoglobinuria and syphilis were not present in group 2, the first case of which was reported

in 1872. Probably wheals from cold have been observed more often than they have been reported. In 1929, Horton and Brown² reported three cases and assembled three more, in which marked systemic histamine like reactions occurred in allergy due to cold. In five of these six, the reactions developed following swimming. One patient in this series was a boy, aged 15, who had received tetanus antitoxin three years previously. In this case the effect of the injection of histamine on

Fig 2—Dermographia from stroking with a fingernail

the blood pressure was studied. After the administration of 0.1 mg, a change was not observed in blood pressure or pulse rate but the boy complained that his face felt hot. After 0.3 mg his systolic blood pressure dropped 9 mm and his pulse increased from 72 to 92. Hemoglobinuria and syphilis were not present in any of these six cases.

REVIEW OF CASE

One cool morning a boy aged 17 on leaving a swimming pool was observed on account of the dusky appearance of the lower half of his body. After swimming he had stood in water above his waist for twenty minutes watching children play. The dusiness extended from the level of the xiphoid process down and over this area were many irregular (probably from coalescence) wheals. Some of these were only a few millimeters in diameter others were perhaps 2 by 6 cm. Considerable itching and burning developed both of which were made worse by scratching. The discomfort passed away in half an hour.

The patient was an only child. His mother died apparently as the result of an accident. His stepmother was subject to hay fever. His previous illnesses included only measles as a child and influenza with pneumonia in 1922. In 1926 he had received diphtheria toxin antitoxin. In 1928 he was pronounced immune to scarlet fever. In 1929 he had been vaccinated again to typhoid and smallpox. He considered himself unusually susceptible to poison oak. Following a small nail wound in August 1929 he was given a large dose of tetanus antitoxin. Four days later he developed a severe generalized rash and was real sick for five days. He had been taking a cold bath each morning and was a prominent athlete at his school.

* Read before the Fulton County Medical Society, Oct. 2, 1930.
1. Harry K. E. Lewis, Thomas and Vaughn J. M. Hemoglobinuria and Urticaria from Cold Occurring Singly or in Combination. Observations Referring Especially to the Mechanism of Urticaria with Some Remarks upon Kayser's Disease. *Heart* 14: 105 (March 24) 1929.

2. Horton B. T. and Brown C. E. Systemic Histamine Like Reactions in Allergy Due to Cold. *Am. J. Med. Sc.* 178: 191 (Aug.) 1929.

Physical examination, including ophthalmoscopy, was essentially negative. At the first determination the systolic blood pressure was 138, the diastolic 86 the boy was obviously excited. Subsequently the systolic blood pressure varied from 114 to 120, and the diastolic from 70 to 84. Hemoglobin was 17.9 Gm and the red cell count was 6,480,000 both in the upper limits of normal according to Wintrobe and Miller.³ The differential count was also normal eosinophils numbering 3 per cent. The Wassermann and Kahn tests and urinalysis were negative.

Fig. 3—The effect of histamine on the pulse and blood pressure of the subject.

Experiment 1 A beaker containing ice water was held on one thigh for about five minutes and one of the same size containing tap water on the other thigh. The pink area left from the beaker with tap water disappeared in a few seconds; the pink area from the cold beaker lasted more than fifteen minutes and seemed to be slightly elevated and rather warmer than the surrounding skin. In a few minutes several wheals appeared varying from 4 to 8 mm in diameter.

Experiment 2 A small block of ice was applied to the thigh for about four minutes. The skin in contact with the ice became markedly blanched and was surrounded by a slightly elevated areola of deep pink. Small wheals appeared in the center.

Experiment 3 Two-tenths milligram of histamine was injected into the subject, and, as a control, 0.3 mg (proportionate to the greater weight) was injected into a normal man, aged 35. Except for flushing of the face with a sensation of warmth in both persons, symptoms were not experienced. A wheal appeared at the site of injection in each person larger in the boy. The subject's systolic pressure dropped more than 20 points two minutes after the hypodermic injection (although not below his systolic pressure at subsequent examinations). At the same time the control's systolic pressure went up.

Experiment 4 The front and back of the thorax was stroked with a comb. Dermographism was pronounced. The subject had grown accustomed to the experiments, and the pulse and blood pressure hardly varied over fifteen minutes. The pulse was 88, the systolic blood pressure 118, the diastolic 76. The skin of the thorax was pink; there was no definite flushing of the face or sensation of warmth.

Experiment 5 The subject sat for twenty minutes in a tub of water at 20°C (68°F). The dry was warm. The skin of the submerged parts became pink and irregular white blotches gradually appeared. There was slight shivering before he left the tub, which was probably responsible for a moderate rise in blood pressure. In less than five minutes the eruption appeared. There were no general symptoms. Twenty-five minutes after leaving the tub, the blood pressure was 122 systolic and 86 diastolic.

COMMENT

The boy was on a brief visit to Atlanta, and it was therefore impossible to repeat the experiments. Facilities were not available to detect fine changes in the temperature of the skin. The possible etiologic significance of the antitoxin of diphtheria and

tetanus is mentioned. There was no history to suggest hemoglobinuria following the urticaria, though actual examination was not done. Lewis and his co-workers, and Horton and Brown were careful to state that reactions in such cases are due to a substance like histamine or very probably to histamine itself.⁴

SUMMARY

A case is presented in which urticarial wheals appeared following prolonged exposure to cold water and in which the response of the blood pressure to histamine was greater than in the control case.

MULTIPLE DIVERTICULA OF JEJUNUM WITH RESECTION*

JOHN R. BOLING, M.D., TAMPA, FLA.

In March 1930 I¹ reported because of its rarity, a case of multiple diverticula of the small intestine. Rothschild, in 1925, collected thirty-three case reports of diverticula of the jejunum, from articles by Balfour Helvestine,² Watson and others.³ Of this number nineteen were multiple, and ten of them were not discovered until operation.

The case I reported was of a man, J. C. H., aged 58, who was operated on in November 1929, for intestinal obstruction. At operation I found in the small intestine an enormous number of diverticula, ranging from the size of a pea to that of a walnut. There was only one of the latter size. It was thought at that time that the involved area was the last part of the jejunum and the first of the ileum. The obstruction was relieved and an enterostomy was done. Since the diverticula did not seem

Section of jejunum 153 cm in length with diverticula

to be causing any trouble at this time nothing more was done. The convalescence was smooth and he left the hospital in good condition. Two months later a gastro-intestinal series was made.

- * Read before Midland Medical Society, Orlando, Fla., Oct. 8, 1930.

³ Wintrobe, M. M. and Miller, M. W. Normal Blood Determinations in the South. Arch. Int. Med. 43: 96 (Jan.) 1929.

with the hope of demonstrating the diverticula. This the roentgenologist failed to do.

Aug 5, 1930, the patient was again admitted to the hospital, with symptoms of intestinal obstruction. Since his discharge in November, he had been in good health, carrying on the work of a farmer.

His present attack began twelve hours before being admitted to the hospital, with general abdominal pain, nausea and vomiting. He took several purgatives with poor results. When he entered the hospital he was comfortable, the abdomen was flat, and an enema gave fair results, both flatus and feces being passed. The white cell count was 10,800, with 80 per cent polymorphonuclears, hemoglobin was 80 per cent, and the urine was negative. He felt all right for the next thirty-six hours, when he was again seized with severe cramping pain, nausea and vomiting. There was general abdominal tenderness with some rigidity and distention. Enemas gave no results and an operation was decided on, the diagnosis being intestinal obstruction and multiple diverticula of the small intestine.

An incision through the old right rectus scar revealed an obstruction caused by the looping of ileum about the adhesion of the enterostomy. This was freed by dissecting the enterostomy area away from the abdominal wall. The intestine was so distended and difficult to control that a suction tube was inserted into the distended loop and a large amount of gas and liquid material was removed.

Since the patient was in good condition, resection of the diverticula-bearing intestine was decided on. On complete exposure of the involved intestine, it was found that the diverticula began about 1 foot (30.5 cm) from the ligament of Treitz and continued down for about 60 inches (152 cm). I was surprised to find the diverticula enormously increased in size since the previous operation. There seemed to be about the same amount of intestine involved, but where before there were three or four small diverticula to a certain space there was now one large one, several small diverticula evidently coalescing to form one large one. Resection of the entire involved intestine was done, an end-to-end anastomosis being made.

He left the table in good condition and reacted well, without any postoperative nausea or vomiting credit for this being largely due to the use of tribrom ethyl alcohol as an anesthetic, only 3 ounces (89 cc) of ether being required.

He has since been entirely free from symptoms and is now back at work.

The section of jejunum was examined by Dr Herbert Mills, who reported that it measured 153 cm. Scattered along the mesenteric surface either in close proximity or at intervals up to 7.5 cm apart were fifty three sessile diverticula, ranging in size from 4 mm in diameter to 3.5 by 5 cm in diameter, averaging about 2 cm. The walls of these diverticula were very thin and translucent the openings of the largest diverticula communicating with the main lumen easily admitting the finger. No other gross pathologic changes were observed.

Microscopic sections showed the mucosa resting on the serosa with no muscular wall between.

I am certain that had roentgenograms been made when the diverticula were large as at the time of the last operation and in the upright position as stressed by Dr J Case in a letter to me the diverticula would have readily been seen.

As I stated in my previous article the causes of diverticula are narrowed down to three, summed up by Sheppe,⁴ in 1924, as

1 Increased abdominal pressure caused by rectal and vesical tenesmus.

2 Atrophy of the inner circular layer of the intestinal musculature.

3 Traction on the intestine by mesenteric vessels shortened by sclerosis and adhesions.

The vast majority are of the false type as was this one.

The history of attacks of indefinite abdominal pain over a period of several years in an old man was suggestive.

The lack of muscular tone in the intestine probably had to do with the first obstruction the last was purely a postoperative one.

DEVICES ALLEGED TO CURE BALDNESS BY MEANS OF ULTRAVIOLET AND INFRA-RED RAYS

W. W. COBLENTZ, PH.D.

WASHINGTON, D. C.

Never has there been such a widespread attempt as today to foist on an unsuspecting and trusting public all sorts of alleged cure-alls to relieve its ills and to keep it in health.

Prominent among these panaceas is the exploitation of ultraviolet and infra-red rays. The mere mention of "infra-red rays" creates in the mind of many persons a feeling that this is something new and mysterious that they have missed, when, as a matter of fact, it is difficult to think of a warm object that does not emit infra-red rays.

When an object is heated to a higher temperature than its surroundings, an excess of infra-red rays passes from it to the surrounding objects. Examples of sources of infra-red rays are arc lamps, incandescent lamps, coal fires, steam pipes, and hot stoves. Because of their low temperature, the infra-red rays emitted by hot water bags and electrical heating pads are of low intensity, and hence they are insignificant in comparison with the amount of heat that is obtained by conduction, by having the hot pad or hot water bottle in contact with the body. Of course it sounds more impressive to speak of infra-red rays than to speak of the application of heat by conduction, by direct contact of the pad with the body.

The trite old saying that a little learning is a dangerous thing seems thoroughly exemplified by the arguments and claims propounded by well meaning salesmen of all sorts of devices offered as cure-alls. Innumerable fallacies are promulgated, especially regarding the penetrating properties of the ultraviolet and the infra-red rays.

It is pathetic and at times ludicrous to hear a promoter of some new device insist that the alleged curative effects are brought about by infra-red rays when common sense observation (exposure of the hand or face to the device) indicates that practically no infra-red rays are emitted and that the heat that is imparted to the body is obtained by conduction by direct contact of the device with the body. To admit this fact makes the device appear commonplace, but "infra-red rays" sounds more impressive.

A ropelike device containing a heating coil, surrounded with a piece of turkish bath towel, which is to be placed over the gums (i. e., surround the mouth, on the outside) was offered as a cure for pyorrhea. The inventor claimed that the infra-red rays had cured his wife of this disease. The infra-red rays emitted were too small in amount to have any effect and even if emitted they could not penetrate the skin.

Another example of infra-red hokum is a dermal-ray cap for making hair grow. This cap was supposed to cure baldness by infra-red rays—a new discovery. As a matter of fact the few infra-red rays that were emitted were of long wavelength, which cannot penetrate the

skin deeper than a small fraction of a millimeter. As will be described later, the heat is obtained by conduction. Granting that infra-red rays have the power to prevent baldness or restore the hair, then in electrical toaster, which is much hotter and emits more infra-red rays, would be more useful than the cap, but, of course, for a bald-headed man to wear an electrical toaster on top of the head for twenty minutes each day would look undignified. So would an electrical heating pad or a hot brick. Hence, the bald-headed portion of the public, ever ready to try a new thing, will probably try the cap, because it is lined with red silk and is said to emit infra-red rays—which it does, but not in sufficient intensity to be effective. Much more heat is obtained by conduction.

Another bit of hokum is a so-called violet ray lamp, consisting of a spark coil to which is attached a glass tube that terminates in a flattened glass bulb that emits a blue glow when it touches the body. The function of this glass tube is to provide a high resistance to the electric current which comes from the spark coil, so that the patient will not feel the shock too severely. The usefulness of such an induction current in the treatment of some diseases is recognized. But to ascribe the healing to the ultraviolet rays emitted by the glass bulb electrode is misleading, for, even if these rays could pass through the glass walls of the bulb they would be too weak in intensity to be effective for therapeutic purposes. There is nothing mysterious in such a device, which is easily made from an old Ford spark coil and a dry battery. Fortunately, the chain drug stores sell them for \$1.39, more or less, and that is not a great loss. But it should not be used as a source of ultraviolet rays, because what few waves are generated are trapped by the glass bulb of the hand electrode.

THE THERMOCAP

The "Thermocap" examined consisted of a cylindrical piece of fiber, attached to a bowl-shaped reflector of aluminum which supported an ordinary Edison lamp socket. The radiator or source of violet rays consisted of an 8 candle power, 110 volt, helical carbon filament incandescent lamp in a bulb of blue glass of the ordinary commercial variety used for decorative purposes and consuming about 0.20 ampere on 110 volts, or between 22 and 23 watts.

The lamp was screwed into the socket at the apex of the dome of the cap and did not make contact with the head. The heat was applied to the scalp principally by radiation, and by conduction through the surrounding air. The device was unwieldy, top heavy, and uncomfortable to wear. The blue bulb lamp was used because the yellow and red rays in the clear glass bulb were supposed to inhibit the biologic action in growing hair.

Thermometric Tests—When the cap was placed on the head, with the room temperature at 22 C (about 72 F) but with no current flowing through the lamp, a thermometer placed at a distance of about 1 cm (one-half inch) above the scalp registered a little above 27 C (81 F). When the lamp was in operation, the temperature increased to 57 C (135 F, at some points, to 58 C, or 138 F). The temperature of the skin is about 36 C (96.8 F). From this, it may be seen that the heat of the lamp can maintain a temperature of about 21 C (57—36) above that of the scalp, while, as noted in the next caption, the blue rays emitted by the lamp can raise the temperature by less than $\frac{1}{2}$, 000 degree C.

Radiometric Tests—The heating effect of the radiation from the lamp was determined by means of a thermopile. Three lamps were tested, all giving closely the same results.

It was found that at a distance of about 4 cm ($\frac{1}{4}$ inches) from the lamp, which is approximately the distance between the scalp and the lamp, the total radiation from the lamp could raise the temperature of a blackened surface by about 1 to 2 degrees C. On the other hand, the intensity of the violet and ultraviolet radiation emanating from this lamp was found to be less than $\frac{1}{10,000}$ of the total radiation emitted. Hence, the rise in temperature that the violet rays could produce was less than $\frac{1}{210,000}$ ($\frac{1}{2}$, 000) degree centigrade.

Spectral transmission measurements were made on a single thickness of one of these lamp bulbs submitted for test, showing a transmission of about 60 per cent in the blue. In other words, if a similar carbon filament were used in a bulb of clear glass instead of blue glass, the intensity of the blue (or shorter) wavelength emitted would be almost double that obtained from the blue lamps employed in the thermocap.

Sunlight Tests—In contrast with the carbon filament, which emits but little violet radiation (even when the filament is enclosed in a clear glass bulb that permits the rays to come out of the bulb), the sun, owing to its high temperature, emits a large amount of blue and violet radiation.

Measurements were made on the blue rays of June sunlight transmitted through a single thickness of a fragment of the blue bulb lamp belonging to a thermocap. It was found that the amount of blue and violet radiation from the sun that is transmitted through this blue glass bulb is sufficient to raise the temperature of a black absorbing surface by about 0.18 degree C when placed in direct sunlight. This is equivalent to a rise in temperature of about 0.3 degree C without the blue glass. In contrast, owing to the low operating temperature of the carbon filament, the violet radiation emitted through the blue glass bulb could raise the temperature only by $\frac{1}{2}$, 000 degree.

In other words, the blue rays of full sunlight can produce a heating effect that is from 10,000 to 15,000 times greater than that of the carbon filament lamp. Near a south window, the intensity of the blue rays of the sky would be from 5 to 10 per cent of this value, or from 500 to 1,500 times that of the blue bulb carbon filament lamp. If the blue rays of such a lamp have a biologic effect in stimulating hair growth, then it should be especially useful to bald-headed visitors to amusement houses illuminated with blue lamps.

THE DERMORY CAP

The "Dermory Cap" examined consisted of an ordinary black silk skull cap lined with red silk. Between the inner red silk lining and the outside of the cap were several turns of asbestos-covered resistance wire, similar to that used in the ordinary felt-covered electrical heating pads. The device consumed about 0.45 ampere on 110 volts, or about 50 watts. Whether the red silk lining was supposed to increase the effectiveness of the infra-red rays in stimulating hair growth was not disclosed. At any rate it would be suggestive.

The dermory cap was evidently intended to be worn in contact with the scalp. At any rate it was unavoidably in contact with the scalp. Hence the heat transfer from the cap to the head was almost entirely by conduction and practically nothing by infra-red rays, as claimed.

Thermometric Tests—The physiologic effect of radiant heat and conducted heat on the skin is to stimulate the nerve endings in the skin, which expands the capillary blood vessels, causing an increase in the blood circulation and erythema.

Accepting this as a basis, I tested the dermoray cap to determine (1) how great a heating effect could be produced on the surface of the skin by the infra-red rays (radiant heat) emitted, and (2) how much heating could be produced by conducted heat.

When the cap was placed on the head, with the room temperature at 22 C (72 F) but with no electric current flowing through the heating wires, a thermometer inserted between the scalp and the lining of the cap registered 36 C (97 F). When the cap was heated, the temperature increased to 59 C (139 F), which was comfortably warm.

Radiometric Tests—The radiant energy test, made by using a sensitive thermopile of bismuth-silver, showed that (assuming that the cap is not in contact with the scalp) the infra-red rays emitted could raise the temperature of the scalp by less than 0.025 degree C, whereas the conducted heat raised the temperature by more than 23 (59—36) degrees C. In other words, the heating by conduction was at least 920 (23—0.025) times more effective than that of the infra-red rays.

But, since the cap touches the head, the heat transfer by infra-red rays is reduced proportionately. If two thirds of the area of the cap is in contact with the scalp, the conducted heat is at least 2,760 (920×3) times as effective as the infra-red rays.

These tests show that practically all the heat is transferred from the cap to the head by heat conduction and only an insignificant amount of heating is produced by infra-red rays. But even if an appreciable amount of infra-red rays were emitted, it would still remain to be proved that the cap will grow hair. Suppose the inventor had claimed that the heat is transferred from the cap to the head by the more obvious and by the really more effective means, viz., as conducted heat, he still would have to prove that it will grow hair.

Council on Pharmacy and Chemistry

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

W. A. PUCKNER, Secretary

PROCAINE BORATE—1 amino benzoyl 2 diethylamino ethanol-penta *m*-borate. β diethylaminoethyl-*p*-amino benzoate penta *m* borate. $\text{C}_6\text{H}_5\text{NHCOOCH}_2\text{N}(\text{C}_2\text{H}_5)_5\text{HBO}$ —A borate formed by the interaction of *p* aminobenzoyl diethylamino-ethanol (procaine base) and boric acid in the same organic solvent. Procaine borate contains 51.8 per cent of *p* amino-benzoyl-diethylaminoethanol.

Actions and Uses—Procaine borate closely resembles procaine hydrochloride in its actions and uses. The molecule is heavier than that of procaine hydrochloride but the toxicity and the anesthetic activity are closely proportional to the procaine base which they contain. When injected subcutaneously, procaine borate exerts a prompt and powerful anesthetic action. It is nonirritant. The testimony concerning its activity when applied to mucous membranes lacks uniformity.

Dosage—For infiltration anesthesia, solutions of 0.5 to 1 per cent for blocking nerves from 1 to 2 per cent for tonsillectomy 0.5 to 1 per cent, mucous surfaces, 2 to 20 per cent, dependent

on the location and the depth of anesthesia required. Its action is enhanced by the addition of a small amount of epinephrine, as in the case of procaine hydrochloride. Owing to the smaller content of the base in procaine borate, the total dose may exceed that of procaine hydrochloride by about 50 per cent.

Procaine borate occurs as a fine white odorless crystalline powder when applied to the tongue it possesses a slightly bitter taste followed by a sense of numbness. permanent in air freely soluble in water about 1 in 4 soluble in alcohol insoluble in acetone benzene chloroform and ether. Its aqueous solution (1 in 10) is alkaline to litmus dissociating hydrolytically. Procaine borate melts at 163 to 166 C.

Transfer about 1 Gm of procaine borate to a suitable Squibb separatory funnel add 25 cc of water followed by the addition of 5 cc of normal sodium hydroxide solution and extract with 5 successive portions of chloroform using 25 cc 20 cc and 10 cc respectively evaporate the combined chloroformic solutions to dryness dissolve the oily semisolid base in 25 cc of a 2 per cent solution of hydrochloric acid portions of the solution respond to the tests for procaine hydrochloride U. S. P. \ p 305. Dissolve 0.1 Gm of procaine borate in 2 cc of methyl alcohol add 5 drops of sulphuric acid and ignite the mixture a green mantle is imparted to the flame. Dissolve 0.5 Gm of procaine borate in 50 cc of water separate portions of 10 cc each yield no opalescence with 1 cc of diluted nitric acid and 1 cc of silver nitrate solution (chloride) no turbidity with 1 cc of diluted hydrochloric acid and 1 cc of barium chloride solution (sulphate) no coloration or precipitation on saturation with hydrogen sulphide (salts of heavy metals). When tested for arsenic according to the U. S. Pharmacopeia \ the product should meet requirements for the arsenic (p 428 Arsenic Test). Transfer about 0.5 Gm procaine borate accurately weighed to a 50 cc glass stoppered cylinder add 25 cc of chloroform and shake the cylinder and contents for five minutes allow to stand until the insoluble portion separates filter, wash the cylinder and the insoluble material onto the filter with two portions of chloroform using 15 cc and 10 cc respectively adding the washings to the original filtrate evaporate the combined filtrates to dryness in a tared beaker and dry to constant weight over sulphuric acid in a partially exhausted desiccator the oily residue should not exceed 2 per cent (limit of uncombined *p* aminobenzoyl diethylaminoethanol).

Dry about 1 Gm of procaine borate accurately weighed over sulphuric acid in a partially exhausted desiccator for forty eight hours the loss does not exceed 2 per cent. Transfer about 0.4 Gm of procaine borate accurately weighed to a suitable Squibb separatory funnel add 25 cc of water followed by the addition of 2 cc of normal sodium hydroxide solution extract with six successive portions of chloroform using 25 cc 20 cc 15 cc 10 cc 10 cc and 10 cc respectively evaporate the combined chloroformic solutions to dryness in a stream of warm air and dry to constant weight over sulphuric acid in a partially exhausted desiccator dissolve the oily residue in about 10 cc of previously neutralized alcohol add 10 cc of tenth normal hydrochloric acid solution followed by the addition of an equal volume of water determine the excess of acid by titration with fiftieth normal sodium hydroxide solution using methyl red as an indicator the amount of tenth normal hydrochloric acid solution consumed corresponds to not less than 50.0 per cent nor more than 52.0 per cent *p* aminobenzoyl diethylamino-ethanol calculated to the dried substance. Titrate about 0.4 Gm of procaine borate to a steam distillation apparatus and determine the m boric acid according to the Gladding method of distillation and subsequent titration (See Leach Food Inspection and Analysis ed 4 p 884) the amount of tenth normal sodium hydroxide solution consumed corresponds to not less than 47.0 per cent nor more than 48.5 per cent m boric acid (HBO) calculated to the dried substance.

Procaine Borate-Searle—A brand of procaine borate N N R

Manufactured by G. D. Searle & Co. Chicago. No U. S. patent or trademark.

Impules Procaine Borate and Epinephrine 1 cc. Procaine borate Searle 0.0216 Gm ($\frac{1}{5}$ grain) and epinephrine 0.00017 Gm ($\frac{1}{100}$ grain) in water to make 1 cc. Each ampule contains more than 1 cc. of solution.

LIVER EXTRACT-FAIRCHILD—A complete concentrate of an aqueous extraction of fresh edible liver, freed of connective tissue lipid and heat coagulable protein. It is marketed in vials each containing the material derived from 100 Gm of the fresh liver.

Action and Uses—Liver extract Fairchild is used in the treatment of pernicious anemia.

Dosage—Liver extract Fairchild is administered orally three four or more vials being given daily until the optimum characteristic effects appear. The content of a vial is placed in a dry glass or cup about 2 ounces of hot or cold water is added and the mixture is stirred constantly until dissolved. It may also be administered in various ways with foods.

Manufactured by Fairchild Bros & Foster New York. No U. S. patent or trademark.

To prepare liver extract Fairchild the fresh edible liver which has been chilled immediately on taking from the body is ground finely with about two volumes of water and macerated for several hours at about 25 C. This is clarified in the usual manner by heating to 60 C. with constant stirring and filtration the residue on the filter press is repeatedly extracted until the wash water is free of water soluble extractives. The entire liquid thus obtained is concentrated in vacuo to a suitable density and is desiccated in vacuo at a low temperature and powdered. The products of many batches are chemically and microbiologically tested to obtain a product of uniform composition. Representative lots are tested clinically to assure potency.

Liver extract Fairchild is a yellowish hyaline granular free soluble in hot or cold water. To an aqueous solution of 1 in 1000 added until the alcoholic content of the mixture is 1 per cent precipitate results.

DEATH FROM EXPLOSION OF MIXTURE OF ANESTHETIC GASES

It has been two years since at Evansville Ind, a tank containing nitrous oxide exploded, killing an anesthetist. The publicity was widespread. Last month a patient died on the operating table in Los Angeles because of the explosion of an anesthetic mixture. Exploitation by the press of such dramatic incidents is natural. Yet the hazard from an explosion of anesthetics, as Henderson¹ has pointed out, is probably less than that of fatally persistent hiccup. At present any death due to explosion receives front page publicity, while a hundred deaths from postoperative pneumonia may not include one mention. Henderson pointedly remarked that surgeons and anesthetists need far more to utilize means to prevent postoperative pneumonia than to worry over the hazard of explosions, except of course explosions due to carelessness.

In the case of the Los Angeles accident, reported elsewhere in this issue,² the patient was given nitrous oxide and oxygen, followed by ether. It has been pointed out repeatedly that a mixture of these gases is explosive, in fact, both ether and ethylene are explosive but only in the presence of oxygen or nitrous oxide. Explosions recorded heretofore appear to have been due to sparks from discharges of static electricity developed in the apparatus for administering the anesthetic. Unfortunately, the conditions that produce explosions are not fully understood. Various committees of the American Medical Association, such as the Committee on Anesthesia Accidents¹ and the Committee on Anesthesia Equipment of the Council on Physical Therapy,³ have drawn up conclusions and recommendations based on available information. Briefly stated, the recommendations of the Committee on Anesthesia Accidents were that the apparatus should be constructed wholly of metal or other material that is a good conductor of electricity so that it would be incapable of developing or

retaining highly localized electrical charges. An equally important measure against sparks or static electricity is to keep the atmosphere of the operating rooms sufficiently moist, a humidity² of 55 per cent is sufficient to prevent the development of electrical charges. In the operating room, or wherever inflammable anesthetics are used, there should be strict rules against any open flame or light. The electrical equipment of the operating room and all suction, heating, radiologic diathermy, and other apparatus should be of good construction and should be kept in such good repair that sparks cannot be produced. Particularly important is it that all electrical apparatus should be so enclosed or so protected that anesthetic gases and vapors cannot reach the electrically charged parts, nor will they be in such proximity to the patient as to induce static sparks. Even with all these precautions there will occasionally be an accident, because explosions due to this cause are largely fortuitous and occur even when obvious precautions are taken. In the Los Angeles accident it appears that the use of diathermy was blamed. The pathologist of the hospital in which the accident occurred has recommended in his letter to THE JOURNAL that physicians should be warned not to use diathermy in the presence of explosive gases. Regrettable as is any case of death from explosion of anesthetic gases, explosion is statistically the least of the hazards of anesthesia.

THE STANDARD AND THE PRESUMPTIVE KAHN REACTIONS

The Kahn reaction has become an accepted procedure for the serum diagnosis of syphilis. There was a time when it seemed that no new method could replace the Wassermann test. About five years ago the Wassermann test was replaced by the Kahn test in the laboratories of the United States Navy and of the Michigan Department of Health. Since that time the Kahn test has replaced the Wassermann in numerous other laboratories and has attained wide use throughout the world as a standard method either with or without the use of the Wassermann test. The superiority of the Kahn test over different Wassermann techniques as well as other precipitation tests is shown by an analysis of the results obtained at the competitive serologic conference of the League of Nations Health Committee held at Copenhagen in 1928.¹ At that conference seven Wassermann methods and seven precipitation tests, including the Kahn, were put to a practical trial in the examination of approximately 1,000 serums, half of which were from syphilitic patients. The Kahn test was one of a group of four methods that did not give positive reactions in the nonsyphilitic cases, and it was more sensitive than the other three to the extent of 20, 45 and 55 per cent, respectively. Among the remaining ten methods that gave varying numbers of

¹ Report of the Second Laboratory Conference on the Serodiagnosis of Syphilis. Geneva. League of Nations Health Organization 1928.

positive reactions in nonsyphilitic cases, one, developed by Prof. Rudolf Muller² of Vienna, exceeded the Kahn in sensitiveness by about 4 per cent. But this method, owing to its impracticability, has since been displaced by Muller in favor of a more recently developed technique.³ The Kahn reaction was thus not only free from false positive results but remarkable for its sensitiveness.

Lately, interest has been directed to the presumptive Kahn test.⁴ This test was developed by Kahn as an auxiliary method to the standard or regular Kahn test, the difference between the two methods being that the presumptive is more sensitive than the regular test. This increased sensitiveness is due to the fact that in the presumptive test "sensitized" Kahn antigen is employed, which possesses a greater degree of sensitiveness than "standard" antigen, used in the regular test. Owing to the possible danger in employing an oversensitive method for the serum diagnosis of syphilis, Kahn believed it best, until the true value of the test is determined, to consider the results presumptive in character. The main functions of the presumptive test are to serve as a technical check on the regular Kahn test and especially as a check on weak and borderline reactions given by that test. The presumptive test being more sensitive, it should give strongly positive reactions whenever the regular test gives borderline reactions. Negative reactions with the presumptive test have greater diagnostic value in eliminating the likelihood of syphilitic infection than similar reactions with the regular test. Positive reactions with the presumptive test aid in establishing a diagnosis of syphilis in isolated cases wherein the regular Kahn test is negative.

McDermott⁵ recently reported on the comparative sensitiveness of the regular and the presumptive Kahn tests based on 15,000 examinations. This worker found the presumptive test to be 26 per cent more sensitive than the regular Kahn test in treated cases of syphilis and 2.5 per cent more sensitive in routine admissions in the University of Michigan Hospital. In spinal fluid tests based on 1,358 examinations the same worker⁶ found the presumptive Kahn test to be 18 per cent more sensitive than the regular Kahn test in treated cases of neurosyphilis and 12 per cent more sensitive in routine admissions. The studies of Davenport⁷ are of especial interest in this connection. This worker found the Kahn test for spinal fluid to be free from false positive reactions but to miss an occasional case of neurosyphilis. Of 118 spinal fluid examinations on patients who presented themselves for

diagnosis, the Kahn test was negative in two cases of neurosyphilis and in three cases of questionable neurosyphilis. Of 369 spinal fluid examinations in treated cases of syphilis, 23 negative Kahn reactions were obtained on the same number of patients who required further central nervous system therapy. The conditions are reversed, however, when the results this worker obtained are compared with the presumptive spinal fluid test. Of 115 examinations on patients who presented themselves for diagnosis, the presumptive Kahn test was positive in 14 patients in various stages of syphilis who showed insufficient clinical evidence of neurosyphilis. One patient with clinical evidence of neurosyphilis, whose spinal fluid gave completely negative serologic results with the colloidal gold, mastix and globulin reactions, and with a cell count of 7, reacted negatively also with the presumptive Kahn test. Turning to treated cases of neurosyphilis, of 359 spinal fluid examinations, 30 were positive in patients in whom no further therapy directed to the central nervous system was indicated. In three patients whose spinal fluids gave negative presumptive reactions, it was deemed advisable to continue central nervous system therapy as a factor of safety; these patients were at work and appeared normal.

Evidently, therefore, the presumptive spinal fluid test is extremely sensitive in detecting changes in the central nervous system due to syphilitic infection. As Davenport points out, his study is too limited to establish that a positive presumptive test on spinal fluid is a diagnostic criterion for neurosyphilis. Meanwhile the method should serve as a stimulus to clinicians to search for evidence of neurosyphilis when the reaction is positive and should play an important part in helping to eliminate neurosyphilis when the reaction is negative.

PHYSIOLOGIC MANIFESTATIONS OF SLEEP

Many textbooks of physiology contain little or no mention of sleep. They may refer to the general manifestations of this state and attach a series of hygienic comments to their descriptions, but theories as to the genesis of sleep are for the most part cautiously avoided. Sleep therefore remains among the riddles of physiology. There are chemical theories that make sleep the result of the action of substances generated during the waking hours and having a soporific effect on the brain. Such conceptions rest on doubtful foundations and are not generally accepted. This is true likewise of the histologic or biophysical theories. These postulate¹ that in the waking state the neighboring nerve units are in contact with each other; transmission of nerve impulses from neuron to neuron is then possible and the result is consciousness. During sleep on the other hand the dendrites

⁷ Davenport K. M. *Am. J. Syph.* 5: 570-575 (Oct.) 1929.

are assumed to be retracted in an ameboid manner, the neurons are therefore separated, and the result is unconsciousness.

More intriguing are the so-called anemia theories of sleep.² They suggest that the alternation between sleeping and waking may be connected with a rhythmic variation in the blood supply to the cerebral cortex. Sleep, with its diminished flow of blood through the brain, is thus represented as a condition of cerebral anemia. Howell, among others, has believed that this follows dilatation of the blood vessels of the skin, such dilatation being due to vasomotor fatigue. Diminished metabolism also has been brought into the category of explanations of sleep. One writer³ argues that it need not be surprising to find that the frequency of the heart as well as that of respiration, retains during this period a value only about three fourths of normal. For the same reason, the blood pressure assumes at this time a level considerably below its usual one. These effects have been made use of repeatedly in explaining the phenomenon of sleep, it being held that the cells composing the higher centers enter this state of depressed function in consequence of a diminution in their blood supply. Thus, he adds it is believed that the volume of the brain decreases during sleep, because a portion of the blood ordinarily allotted to this organ is temporarily diverted into the portal and cutaneous circuits.

The recent careful investigations of Grollman⁴ at Johns Hopkins University seem to upset many of the current assumptions. He has observed that the decreases in cardiac output, blood pressure and oxygen consumption during sleep are of the same order of magnitude and such as would be expected to occur in complete rest. This fact, Grollman avers, renders improbable the view that sleep is attended by any marked vasomotor changes, redistribution of blood, cerebral anemia, or splanchnic congestion as held by earlier workers. It is worthy of emphasis that these experiments, like those of Hill and Pieron, refute the idea that the blood pressure is lower during sleep than when the subject is awake. That is, there is no specific change in the blood pressure that is associated with the sleeping state, but the observed values occur irrespective of whether the subject is asleep or awake, so long as he is completely at rest. Furthermore, the sleeping state is not characterized by any peculiar diminution in the metabolism as compared to the waking state at the same hour of the night. The oxygen consumption decreases rapidly in the early hours of the night to a minimum early in the morning which is about 10 per cent lower than the basal value as observed in the morning after awakening. If the cardiovascular and metabolic functions are excluded from the causation of the somnolent

state, and changes in them are merely incidents in the physiologic cycles, other causes of sleep must be discovered. This paves the way for considerations of sleep as a process of inhibition, such as Pavlov has championed.

IODIZED MILK

The current enthusiasm for child welfare, with all that it implies for prenatal care and for growth, development and maternal care, was reflected in the recent White House Conference on Child Health and Protection. The number of health items that arouse concern seems to be growing with the years. Child psychology has of late required an enormous impetus. In the domain of bodily health, preventive medicine is forging ahead rapidly. There are "well baby clinics" that vie with "sick baby clinics." Vaccination against smallpox and immunization against diphtheria are becoming routine measures in well managed communities. Dental hygiene has placed specialists at the call of the schools. To these features may be added a widespread concern about the proper development of the thyroid gland and the attempts to avert adolescent goiter. The extensive occurrence of such thyroid abnormality in this country has become familiar. Details have repeatedly been rehearsed in THE JOURNAL.

The goiter regions of the United States are characterized as a rule by a smaller content of iodine in the vegetation and local edible foods. Analyses of drinking water obtained from nongoitrous regions show higher iodine values than those obtained from regions where goiter is prevalent.¹ The association of endemic goiter with a lack of iodine was reported in 1921 by Marine and Kimball.² As is now well known, the commonest prophylactic measures have involved the periodic administration of therapeutic doses of iodide or other iodine-bearing compounds to school children. Other measures have consisted in the addition of inorganic iodides to the drinking water supply and to table salt.

It is now an established fact, as Krauss and Monroe³ have recently remarked, that the iodine content of milk can be materially increased by feeding cows some source of inorganic iodine, such as potassium iodide, or some source of organic iodine, such as kelp. Considerable milk containing more than a normal amount of iodine is probably being produced through the feeding of iodized mineral mixtures and commercial preparations made up of substances that contain iodine. It is also well known that the iodine content of milk may vary from a trace to several parts per million, depending on regional influences. Supplee⁴ has made analytic

⁴ Supplee, G. C. Seasonal Variations in Certain Inorganic Constituents of Dry Milk Produced in New York and Wisconsin. *J. Dairy Sci.* 13: 522 (Nov.) 1930.

comparisons of the iodine content of representative dry milk powders prepared every month of the year from milks produced in Wisconsin and New York, respectively. The outcome was perhaps somewhat unexpected. The powder from the New York territory, summer production, contained 145 parts of iodine per billion, the winter production from the same territory contained 67 parts per billion. The powder from the Wisconsin territory, summer production, contained 704 parts of iodine per billion, the winter production from the same territory contained 961 parts per billion.

The experimental studies of Kruss and Monroe at the Ohio Agricultural Experiment Station in Wooster leave little doubt that "naturally iodized" milk can exert an influence in goiter prophylaxis. In tests on susceptible animals, iodized milk, secured by feeding 0.1 Gm of potassium iodide daily to cows, was compared with normal milk and with normal milk plus different amounts of potassium iodide. Prophylactic and curative methods were employed. In general, smaller thyroid glands containing a greater percentage of iodine resulted whenever iodized milk or potassium iodide was fed than when "normal" milk of the region was used.

The Ohio biochemists remark that iodizing the general milk supply would insure a constant source of iodine to all persons using milk. It would automatically treat a great many individuals who either through ignorance or lack of funds have had no knowledge of a thyroid deficiency. It would serve as a prophylactic, particularly in young growing children, when an iodine deficiency has not manifested itself in any symptom ordinarily used in diagnosis. Furthermore, the iodine would be furnished in a stable, convenient and pleasant form. On the other hand, they add, in cases in which a constant supply of iodine would be irritating rather than beneficial, some source of ordinary or noniodized milk would need to be available. It is true that putting iodine into milk through the cow is rather wasteful, as only from 10 to 15 per cent of the iodine fed appears in the milk, but by such a procedure the cow also is benefited. Recent studies by Hanzlik and his associates⁵ and of Mendel and Vickery⁶ make it seem unlikely that normal growth will be interfered with by the continued administration of iodide in small daily doses. Nevertheless there is a widespread belief that adolescents as well as adults should not be subjected indiscriminately to a surplus of iodine in all sorts of ingested foods, condiments and drink. Goiter prophylaxis ought to be placed on a quantitative dosage basis. Milk doubtless can be made useful in such endeavors as can other food products. The mode of preference should be left to the physician, however, and not to the food propagandist.

Current Comment

HOUSE COMMITTEE REPORTS ON FEDERAL AID FOR MATERNAL HYGIENE

The Committee on Interstate and Foreign Commerce of the House of Representatives has recommended that the bill passed by the Senate (S 255) to authorize federal subsidies for the promotion of intrastate activities in the fields of maternal and infant hygiene, under the supervision and control of the federal government, be amended to provide federal subsidies for the promotion of intrastate rural hygiene also, under similar supervision and control, and be then enacted. The bill as thus amended has the endorsement of the Secretary of the Interior and of the Secretary of Labor, and the qualified endorsement of the Secretary of the Treasury. It is commonly understood to have the tacit endorsement of the President. The report of the committee, however, does not contain evidence to show that former legislation of this type in the field of maternal and infant hygiene accelerated the decline of infant and maternal death rates, after seven years' effort and eleven million dollars' expense. The report does not provide evidence to show that there is greater need for federal aid in the promotion of health in rural areas, which it is proposed to benefit by this bill, than in urban areas, which the bill ignores. Probably the committee found no such evidence. In view of the strong disapproval by the administration of federal financial aid, even temporarily, to the people of certain states now in dire distress, it is difficult to comprehend the reasoning by which the administration approves continuing permanent federal aid of the character proposed by this bill. *THE JOURNAL* must continue to protest against the subordination of the constitutional rights of the states to federal control and the promotion of the growth of the federal bureaucracy.

STATISTICS ON CANCER

The British government, about ten years ago, had a quantity of radium available, which was entrusted to the Medical Research Council of England to be used in the treatment of cancer. The council lent this radium to institutions located at centers of population where a general hospital and a university medical school worked in conjunction with the investigators of radium. The council has recently published a report¹ of the results obtained from eleven such institutions. It shows that only a small number of cases of carcinoma were treated during the first five years of the survey. Recently the number of patients treated has increased considerably. It is too soon, however, to draw any conclusions as to the final results. The report brings out one promising feature in the treatment of cancer. Radium was used in the treatment of carcinomas of the breast in a relatively small series. In a fifth of the cases, pronounced inoperable by surgeons, the patients were alive without apparent signs of disease two or three years after treatment. Somewhat similar results were

¹ Medical Uses of Radium. Special Report Series, number 14. Medical Research Council, London, 1933.

reported with inoperable carcinoma of the cervix, although none of the patients treated more than five years previously were alive. This would indicate that physicians may consider treatment by radium or x-rays of any inoperable case, no matter how hopeless the possibilities may seem. In a few years England will have excellent statistics on the treatment of cancer by radium. A national organization might undertake and enlarge on a similar plan in this country. Such control is needed especially because lenders of radium for commercial purposes now urge its use in unsuitable cases by men not specially trained in its application. There is apparently no correlation of results of treatment of cancer by radium in the various parts of our country. Physicians must rely on reports in the literature, which are frequently contradictory. A yearly national report should be made, as is done in England. It could be enlarged to include the final results of all cases of cancer, whether treated by radium, x-rays or surgery. If all the medical centers were included in this survey, it would be only a few years until some impartial figures of considerable proportions would be available indicating the prognosis and the best treatment for the various types of cancer.

MEDICAL BROADCAST FOR THE WEEK

American Medical Association Health Talks

The American Medical Association broadcasts at 10 a. m. on Monday, 10:45 on Tuesday, 10:45 on Thursday and 10 o'clock on Saturday, over Station WBBM (770 kilocycles or 389.4 meters).

The program for the week is as follows:

February 16	Another It's—Sinusitis
February 17	Worn Out Filters
February 19	Your Child's Eyes
February 21	It May Be Your Teeth

Five Minute Health Talks may be heard over the Columbia Broadcasting System daily except Sundays and Holidays from 12 to 12:05 p. m.

The program for the week is as follows:

February 16	The First Week
February 17	Sinits
February 18	Too Much Coddling
February 19	Why People Get Sick
February 20	The Art of Accepting Affliction
February 21	Food Habits for Children

Bill Introduced—S. 37 proposes to require all applicants for licenses to practice any form of the healing art to pass examinations in anatomy, physiology, chemistry, bacteriology, pathology and hygiene, given by a board of examiners in the basic sciences prior to being permitted to present themselves for examination before their respective professional or cult licensing boards.

CALIFORNIA

Bills Introduced—A. 1501 proposes to amend the definition of the practice of dentistry so as to prohibit a licensed physician from practicing oral surgery. A. 1502 proposes to amend the procedure to be followed in revoking or suspending licenses to practice dentistry. A. 1503 proposes to designate the following practices 'unprofessional conduct and as such sufficient cause for the revocation of licenses to practice dentistry: (1) aiding or abetting any unlicensed individual to practice dentistry unlawfully and (2) practicing or advertising under a false, assumed or fictitious name either as an individual firm or corporation. A. 1504 proposes to make it a misdemeanor for any person to practice, or to advertise or in any other manner indicate that he is practicing or will practice dentistry, under a false, assumed or fictitious name.

Report of Tropical Disease Clinic—The Institute of Tropical Medicine of the University of California, San Francisco, gave 445 treatments to eighty-three patients in its first year of service. According to Dr. Alfred C. Reed, director, in a report for the period from Sept. 1, 1929, to Sept. 1, 1930, thirty Americans, eighteen Filipinos, nine Mexicans, eight South Americans and Central Americans and eighteen others of miscellaneous nationalities received an average of more than five treatments each. Among the diseases found were leprosy, pellagra, granuloma inguinale, elephantiasis, dysenteries, intestinal parasites and malaria. The number of patients referred to the University Hospital has increased each month since the establishment of the institute it is said, and, in some cases, patients are referred back to their physicians with full reports and recommendations for treatment. Patients able to pay a fee are referred to physicians who specialize in this kind of work but the institute cares for indigent patients. Out of town patients must be prepared to pay for lodging outside the hospital as the clinic has no facilities for patients who are not confined to bed.

Death from Explosion of Mixture of Anesthetic Gases—In a laparotomy in a Los Angeles hospital, a woman aged 43, was given nitrous oxide and oxygen. After incision was made in the abdominal wall, because the depth of the anesthesia was not sufficient, ether was added to the mixture. A few moments later an explosion occurred. A request for information by THE JOURNAL elicited the fact that the explosion was confined apparently to the mixed gases in the anesthetic mask and in the lungs. Immediately after the explosion the patient stopped breathing and could not be resuscitated. The explosion lifted the mask about an inch or more from the face. There was a slightly charred or burned area on the chin. At necropsy, innumerable variously sized hemorrhagic areas due to rupture of alveoli and bronchioles were found in the lungs, also four small holes about one-fourth inch in diameter were found passing through the visceral pleura on the inner border of the left lung. While the cause of the explosion is not definite, it appears that diathermy was applied during the operation. As all other sources of sparks had been eliminated, according to the report sent to THE JOURNAL it would seem that the elec-

trostatic field, developed in and on the patient by these high frequency currents, may have been the primary cause. A tiny spark probably jumped from some individual near the patient or from shifting or slightly raising the mask, thus igniting the explosive mixture of gases.

COLORADO

Bill Introduced—H 266 proposes to amend the state prohibition law to conform with the Volstead Act with respect to the amount and frequency of a physician's prescribing of liquor.

Society News—Dr Tom R Knowles, Colorado Springs, was elected president of the Arkansas Valley Medical Association, January 10, succeeding Dr Lanning E Likes of Lamar. Among the speakers on the program were Drs Alfred H Washburn, Denver, and Lewis J Moorman, Oklahoma City, whose subjects were "Prevention of Heart Disorders in Early Life" and "Simultaneous Bilateral Collapse in Treatment of Tuberculosis," respectively. Dr Burton B Grover addressed the El Paso County Medical Society, Colorado Springs, February 11, on "Electrosurgery", Dr Arthur J Markley, Denver, presented a report of the International Dermatological Congress in Copenhagen.

CONNECTICUT

Bill Introduced—H 111 proposes (1) to repeal that provision of the medical practice act which exempts applicants who graduated from medical colleges prior to Jan 1, 1919 or who were eligible to examination before that date, from the requirement of having had prior to beginning the study of medicine, nine months work in chemistry, physics and general biology, and (2) to eliminate the fee of \$15 for approving the credentials of an applicant for a license by reciprocity.

ILLINOIS

Society News—Dr Ralph C Hamill, Chicago, addressed the Champaign County Medical Society, February 12, on prevention of nervous disorders. Dr Julius H Hess, Chicago, will address the Rock Island County Medical Society, February 15 on "Focal Infections of Childhood". Dr James H Hutton, Chicago, addressed the Vermilion County Medical Society, Danville, February 3, on "Endocrine Disorders Occurring in General Medicine," and the DeWitt County Medical Society, Clinton, February 11, on "Diagnosis and Treatment of Common Endocrine Disorders."

Chicago

Institute for Hospital Boards—An institute for lay boards of hospitals and public health nursing organizations will be held in Chicago February 17, under the auspices of the Central Council for Nursing Education concurrently with the annual congress on medical education, licensure and hospitals. Among the speakers will be Carl E Buck, DPH, Detroit, on "Responsibility of the Citizen for Community Health", Dr Henry S Houghton, Iowa City, The State University and Nursing Education, Miss Isabel Stewart, of Columbia University, New York, on 'The Present Trend in Nursing Education' and Miss Adda Eldredge, Madison Wis, Relation of the School of Nursing to the Board of Directors. At a dinner given jointly with the Council on Medical Education and Hospitals of the American Medical Association Monday evening February 16, Dr Henry A Christian, Boston, will speak on "The Clinic as a Center of Graduate Study."

Society News—Dr Vilrav P Blair, St Louis will deliver the seventh Lewis Linn McArthur lecture of the Billings Foundation of the Institute of Medicine of Chicago before the institute and the Chicago Surgical Society February 27 on "Facial Abnormalities Fancied and Real the Reaction of the Patient, and Their Attempted Correction". Dr George Milles, among others, addressed the Chicago Pathological Society, February 9 on "Primary Carcinoma of the Jejunum". A McCrea, PhD, Detroit addressed the Chicago Council of Medical Women February 6 on "Parasitic Fungi of the Skin," and Rosalie M Parr, PhD, "Effects of Germanium and Selenium Compounds on Blood Morphology". The Society of Medical History of Chicago will be addressed February 20 at the Archibald Church Library, Northwestern University, 303 East Chicago Avenue by Dr M Herbert Barker on "Richard Bright and His Contribution to Renal Pathology", J Barry Anson, PhD, Thomas Willis and His Contribution to Anatomy, and Dr Irving S Cutter, "A Brief Description of Some Source Items in the Church Library". The annual conference of the Chicago Association for Child Study and

Parent Education will be held at the Palmer House, March 28. The tentative program includes papers by Dr Lawson G Lowrey, director, Institute for Child Guidance, New York, on "Some Emotional Difficulties in Marital Adjustment Related to Early Parental Patterns", Dr Bernard Glueck, New York, "Some of the Sources of Marital Discontent", Phyllis Blanchard, PhD, of the Philadelphia Child Guidance Clinic, "Personality Problems in Marriage and Parenthood," and Floyd Dell, author, "The Family and the Machine Age". In a symposium on urinary lesions held by the Chicago Roentgen Society, February 11, speakers were Drs Bernard H Nichols, Cleveland, on iopax, Herman L Kretschmer, pyelography and Ursus V Portmann, Cleveland "Irradiation Treatment of Malignant Urinary Lesions". Dr Bowman C Crowell presented a paper on differential diagnosis of giant cell tumor before the Chicago Orthopedic Club February 13. Dr Clark W Finnerud, among others, will address the Chicago Ophthalmological Society, February 16, on "Skin Diseases of the Eyelids". Dr William L Beecher will speak on "Hyperesthetic Rhinitis and Asthma Due to Digestive Ferments" before the Chicago Society of Allergy, February 16. A symposium on sterility will be conducted before a joint meeting of the Chicago Gynecological and Urological societies, February 26. Dr Rudolf Schonheimer, director, Biochemical Laboratory of the Pathological Institute, University of Freiburg, Germany, addressed the Medical Research Club of the University of Illinois, January 28 on "Recent Advances in Our Knowledge of Cholesterol Metabolism."

INDIANA

Bills Introduced—S 96 proposes to require the annual registration of registered nurses and trained attendants and the payment of an annual fee of \$1 and of 50 cents, respectively. H 32 proposes to grant financial aid to any county, or to any two or more counties which may hereafter establish and maintain a hospital for the care and treatment of persons suffering from tuberculosis, or to any county which does not maintain such hospital but which contracts with another county for the care and treatment of such persons. H 246 proposes to provide that in every city of 3,000 or more population the board of health make medical inspections from time to time of all persons attending or employed in public, private and parochial schools. H 304 proposes to authorize a court or jury to order the sexual sterilization of any person convicted of murder, burglary, robbery, banditry, arson, rape or the commission of any other felony in which life is threatened.

IOWA

Bills Introduced—S 56 proposes to amend the law with respect to coroners by allowing a coroner, if he is a licensed physician to perform autopsies. H 31 proposes to define podiatrists as persons who publically profess to be podiatrists or who publically profess to assume the duties incident to the practice of podiatry or who publically profess to treat ailments of the human foot persons who diagnose or give medical or surgical treatment to ailments of the human foot.

Society News—Among speakers at the meeting of the Sioux Valley Medical Society, Sioux City, January 20-21 were Drs Raphael Isaacs, Ann Arbor, Mich, on "Different Types of Anemia: Diagnosis and Treatment", Sumner L Koch, Chicago, "Acquired Contractures of the Hand", William W Duke, Kansas City, allergy, W McKim Marriott, St Louis, care and feeding of infants and children, Edward C Roscnow, Rochester, Minn, focal infection, Frederick A Willis, Rochester, Minn, treatment of heart failure, Frederic F B Foley, Minneapolis, surgical treatment of hydronephrosis and Ralph M Waters, Madison Wis, oxygen and carbon dioxide variations accompanying the relief of pain.

KANSAS

Bills Introduced—H 26 to amend that section of the workmen's compensation act stating the amount for which an employer will be liable for medical attention rendered an injured employee, proposes that such liability shall extend to such medical surgical or other attendance or treatment nursing, or hospital service, medicine crutches and apparatus as may be necessary during sixty days after the injury or for such time as the industrial commission may order. An employee or another in his behalf may obtain emergency treatment at the expense of the employer. H 267 proposes that the provisions of the narcotic act shall not apply to decocted or infused or preparations made therefrom or to other preparations of coca leaves which do not contain cocaine.

Society News—The Allen County Medical Society devoted a recent meeting to a discussion of poliomyelitis, among the speakers were Drs. Rexford L. Dwyer and Frank C. Neff, Kansas City, and Clarence H. Kimmman of the state board of health, Topeka.—Dr. Arthur L. Strauss, St. Louis, addressed the annual meeting of the Shawnee County Medical Society, Dec. 1, 1930, on myocarditis.—The Kansas City Southwest Clinical Society held its monthly clinic, January 13, at Research Hospital. Dr. William I. Coughlin, St. Louis, spoke on "Diagnosis and Treatment of the Acute Abdomen," he also addressed a joint meeting of the Jackson and Wymondotte county medical societies on sympathectomy in arthritis.—Plans for a year's investigation in high blood pressure have been announced by the University of Kansas School of Medicine. Dr. John B. Nimmer, will carry on the research which is financed partly by a grant of \$1000 from the National Research Council.—Drs. Earl C. Padgett and Leroy A. Calkins addressed the Wymondotte County Medical Society, January 6, on "Relative Position of Kidney and Surgery in Cancer of the Face, Mouth and Jaws" and "Use of Radium in Gynecology," respectively. The society was addressed February 3, by Drs. Fred I. Angle, Kansas City, and Joseph E. Weller, Kansas City, Mo., on "Treatment of Acute Cardiac Embarrassment Without Edema" and "Treatment of the Cardiac Patient with Edema," respectively.—Dr. George C. Lee, Kansas City, Mo., addressed the Bourbon County Medical Society, Dec. 15, 1930, on "Disorders of the Heart."—Dr. Carl F. Nelson, Lawrence, addressed the Sumner County Medical Society, Dec. 18, 1930, on "Causes, Effects and Treatment of Acute and Chronic Oxygen Want" and Dr. Ira H. Dillon, Wellington, "Conservatism in the Treatment of Nasal Accessory Sinus Infections."

MAINE

Bill Introduced—S. 153 proposes to permit cities and towns to appropriate money to be expended in the city or town where appropriated, under the direction of the state department of health, for dental hygienist service.

MARYLAND

Professors Welch and Howell to Retire—Dr. William H. Welch, professor of the history of medicine, and Dr. William H. Howell, professor of physiology and director of the School of Hygiene and Public Health, Johns Hopkins University, will retire in June. Dr. Welch, who will be 81 in April, was the first professor of pathology at Johns Hopkins University School of Medicine, having served in that capacity from 1884 until 1916 when he became the first director of the School of Hygiene and Public Health. In 1926 he resigned that position to accept the newly created chair of the history of medicine. The new medical library at Johns Hopkins dedicated in 1929 is named for him. Dr. Welch's eightieth birthday was marked by an international celebration. Dr. Howell, who will be 71 this month, has been professor of physiology since 1893. In 1926 he succeeded Dr. Welch as director of the School of Public Health and Hygiene. He is the author of a textbook on physiology and was president of the International Physiological Congress in 1929 when it met in Boston. Dr. Welch was the guest of honor at a dinner at the Maryland Club, Baltimore, January 28, at which Dr. Howell presented to him a volume bearing congratulatory messages from friends. John D. Rockefeller, Jr., also presented a volume recounting the eightieth birthday celebration.

MASSACHUSETTS

Bills Introduced—S. 222 proposes to regulate the practices of hair dressers, cosmetologists and electrologists. A cosmetologist would be permitted to remove superfluous hair, warts and moles from the body of any female by the use of electricity, or otherwise, and an electrologist would be permitted to remove superfluous hair, warts or moles from the body of any person by use of electricity. H. 265 proposes to extend the provisions of the vaccination law to private schools.

District Society Celebrates Ninetieth Anniversary—The Essex North District Medical Society celebrated the ninetyeth anniversary of its founding at a meeting, January 7, at the Groveland Congregational Church where the first meetings were held in 1841. Dr. Frank W. Snow, Newburyport, outlined the history of medicine in the district and the formation of the society. In eighty-seven years there have been only four secretaries of the society. Drs. Francis W. Anthony, Haverhill, and I. Forrest Burnham, Lawrence, read other historical papers. Miss Helen King Spofford, granddaughter of Dr. Jere-

miah Spofford, one of the founders, exhibited for the society a collection of her grandfather's old medical instruments, books and documents. Other unique articles were shown, including a string of sleigh bells tuned so that citizens might recognize the doctor's approach.

MINNESOTA

Bills Introduced—H. 300 proposes to regulate the practice of naturopathy. A proposed board of naturopathic examiners would be authorized to issue certificates to all present naturopathic practitioners, which would entitle the holders to certificates of registration in the basic sciences without examination. Thereafter all naturopathic applicants, however, would be examined in the basic sciences. Naturopathy is said to be "non-medical and drugless and is defined as the science and art of nature cure, or of naturopathy, its science being the use of such natural, corrective, vital and purifying therapeutic agencies as will enable the human organism to free itself of abnormal and toxic conditions and to set up such inherent healing processes as will restore and maintain the highest possible degree of health, that such restorative methods include all physical means and instrumentation applicable in the scientific uses of sunlight, air, water, earth, food, the non-narcotic vegetable herbs and the magnetic, electric and etheric energies that have therapeutic relation to the biological laws and processes of life." H. 301 to amend the basic science act, proposes to designate specifically the practice of naturopathy as a branch of the healing art to which the basic science act applies and to add one doctor of naturopathy to the board of examiners in the basic sciences.

MISSOURI

Society News—Dr. Emmett P. North was elected president of the Missouri Pacific Hospital Association, January 31. Dr. James R. McLean, Kansas City, vice president, and Dr. Henry J. Schenck, St. Louis, secretary.—Dr. Geza de Lukits, Chicago, addressed the Jackson County Medical Society, February 10, on "Surgery in Diabetic Patients" and Dr. Clay S. Merriman, Kansas City, "Cause and Treatment of Diabetes."

Bills Introduced—S. 44 proposes to repeal the state prohibition law. H. 220 proposes that any bail or trust company may engage in the practice of medicine, surgery, dentistry or chiropractic without examination and without securing any license to practice, to the same extent and in the same manner that banks and trust companies may now practice law. H. 223 proposes to authorize the mayor and board of aldermen of cities of the fourth class, among other things, to regulate and license and to levy and collect a license tax on, druggists and the owners or managers of private venereal hospitals.

NEBRASKA

Bill Introduced—H. 309 proposes to authorize trial judges when in the trial of a cause the mental state of the defendant at the time of the commission of the offense is at issue, to appoint one or more but not to exceed three, expert witnesses. The state and the defendant, however, shall have the right to call their own expert witnesses.

License Revoked—According to the department of public welfare, the license of Dr. George L. Wagner, Deshler, to practice medicine in Nebraska was revoked, Nov. 19, 1930, following his failure to obey the order contained in a suspended sentence of the department of public welfare, Oct. 31, 1930, that he submit himself to an institution and take the alcoholic cure.

NEW JERSEY

Bill Introduced—A. 101 to amend the workmen's compensation act, proposes to designate as "radium poisoning" that occupational disease now listed as "radium necrosis."

Society News—Drs. Arthur J. Casselman and Hyman I. Goldstein, among others, addressed the Camden County Medical Society, February 3, at Camden, on "Loss of Sugar Tolerance in a Diabetic" and "Streptococcus Faecalis with Erythema Nodosum and Erythema Multiforme Exudativum."—Dr. Clay Ray Murray, New York, addressed the Atlantic County Medical Society, February 13, on treatment of fractures.

NEW MEXICO

Bills Introduced—S. 21 and H. 40 propose to create a board of barber examiners and to regulate the practice of barbering. H. 40 has passed the House. H. 32 proposes to create a board of naturopathic examiners and to regulate the practice of naturopathy. Such a practitioner may "diagnose

and treat diseases, injuries, deformities, or other physical or mental conditions, including the practice of obstetrics, by the use of any or all methods, such as palpating, diagnosing, and treating diseases, injuries, and defects of human beings by all known means of naturopathy, including among other things all natural agencies imbued with the healing art such as food, water, heat, cold electricity, vacuum cupping, mechanical appliances, and heliotherapy, provided however that nothing in this act shall be construed to permit the use of major surgery, serums and vaccines, and narcotic drugs."

NEW YORK

Old Age Security Plan Goes Into Effect—The New York State Old Age Security Plan became effective, January 1. This is based on a contributory system, it is reported, which means that every person in the state, whatever his circumstances, will contribute to the cost of this new plan for the relief of the aged, either in the form of a direct tax for purposes of the state government which will include this item or in the form of an increased cost of living by which direct taxation is filtered through the entire community.

Bills Introduced—H 432 proposes to modify the limitations placed by law on the practice of physiotherapy by technicians by allowing such technicians to use, in the treatment of diseases without the supervision of a licensed physician, actinotherapy, hydrotherapy, mechanotherapy, thermotherapy, and electrotherapy exclusive of the x-ray. S 345 and A 441 propose to provide that whenever a defendant's insanity or mental condition at the time of the commission of an offense becomes the issue in any criminal cause the court may appoint one or more but not exceeding three disinterested legally certified psychiatrists to examine the defendant. The appointment of such experts by the court shall not preclude the state or the defendant from calling additional expert witnesses. A 369 proposes to create a board of barber examiners and to regulate the practice of barbering.

New York City

Fifth Harvey Lecture—Edward M. East, LL.D., Harvard University, Cambridge, will deliver the fifth Harvey Society Lecture at the New York Academy of Medicine, February 19, on "Possible Immunologic Reactions with Plants."

Dr. Levene Receives Gibbs Medal—Dr. Phoebus A. Levene of the Rockefeller Institute has been awarded the Willard Gibbs Medal by the Chicago section of the American Chemical Society. This is said to be the highest chemical award in the United States and is the third time in twenty awards that a biochemist has been the recipient. Dr. Levene received the award for his work in the application of organic chemistry to biologic problems. His research in nucleic acids, amino sugars and lecithins is particularly mentioned. Dr. Levene has been assistant in chemistry since 1905 and member, since 1907, of the Rockefeller Institute. He also has an M.D. degree from the Imperial Military Medical Academy, St. Petersburg (1891). The award will be made in May.

Seminar in Physical Therapy—The New York Physical Therapy Society is sponsoring a seminar in physical therapy which will consist of didactic lectures and clinical demonstrations. The program opened February 4 with "Clinical Uses of Ultraviolet Radiation" by Dr. Edgar Mayer, Syracuse, N. Y. Edward E. Free, Ph.D., New York, spoke February 11, on "Physics of Ultraviolet Radiation" and will speak February 18 on "Physics of Photo and Heat Therapy." The following lectures will be given in Beth Israel Hospital, February 25: "George H. Vaughan, Ph.D., Cornell University, Ithaca, 'Physiology of Ultraviolet Radiation'"; and Dr. George M. MacKee, New York Post Graduate Medical School and Hospital, "Effect of Ultraviolet in Cutaneous Conditions." March 4, Dr. Ralph Pemberton, Graduate School of Medicine of the University of Pennsylvania, Philadelphia, "Massage." March 11, Harold J. Holmquist, B.S., Chicago, "Physics of Medical Electricity." March 18, Dr. William D. McKeefe, Boston, "Electrostatic Therapy." March 25, Dr. Frank H. Krusen, Temple University School of Medicine, Philadelphia, "Low Voltage Currents." April 1, Dr. Chas. Ray Murray, Columbia University College of Physicians and Surgeons, "Physical Therapy in Fractures." April 8, Dr. Harry Eaton Stewart, New Haven School of Physical Therapy, New Haven, Conn., "Medical Diathermy." April 15, Dr. William F. Schmidt, Philadelphia, "Surgical Diathermy." April 22, Dr. Josef B. Nixlin, Philadelphia, "Hydrotherapy." April 29, Dr. Francis G. Harrison, Graduate School of Medicine, University of Pennsylvania, Philadelphia, "Physical Therapy in Urology," May 6,

Dr. Francis Carter Wood, "Indications and Contraindications of X-Ray Radiation," and Dr. George M. MacKee, "Treatment of Cutaneous Cancer and Precancerous Lesions," May 13, Dr. Walter I. Galland, New York, "Physical Therapy in Orthopedics," May 20, Dr. Grant E. Ward, Baltimore, "Physical Therapy in Gynecology," May 27, Dr. Royal Storr Haynes, New York, "Posture as a Therapeutic Procedure," and Dr. Kristian G. Hansson, New York, "Posture and Exercise in Adults."

Society News—Dr. Priscilla White, Boston, among others addressed the Women's Medical Association of New York City, January 14, on "Care of the Diabetic Child."—Dr. William Wayne Babcock, Philadelphia, among others, addressed the Medical Society of the County of Kings, January 20, on "Practical Application of Spinal Anesthesia."—Dr. George Brehr spoke on "Diagnosis of Visceral Manifestations of Syphilis" before the Brooklyn Society of Internal Medicine, January 23.—Dr. David Ayman, Boston, addressed the Medical Society of Bay Ridge, Brooklyn, January 13, on "Early Diagnosis and Early Treatment of Essential (Arterio) Hypertension."—Drs. George W. Crile, Cleveland, Dean Lewis, Baltimore, and William F. Rienhoff, Jr., Baltimore, took part in a symposium on thyroid disease presented by the Medical Society of the County of New York, January 26. Dr. Charles Gordon Heyd, newly elected president, delivered his inaugural address on "Economic Contribution of Physicians to the Community."—Dr. Russell S. Ferguson addressed the Medical Association of the Greater City of New York, January 19, on "Treatment of Cancer of the Prostate by Radiation," and Dr. George F. Cahill on renal tuberculosis. Dr. Le Grand Kerr was elected president.—The ninth afternoon lecture for practitioners in the series sponsored by the New York Academy of Medicine was given January 23, by Dr. Joseph F. McCarthy on "Roentgenographic Delineation of the Urogenital Tract." Dr. Edward P. Carter, Baltimore, delivered the tenth lecture, January 30, on "Certain Aspects of Syphilitic Cardiac Disease," and Dr. Dorn Lewis, Baltimore, the eleventh, February 6, on osteomyelitis.—Speakers at the Yorkville Medical Society in the City of New York, January 19, were Drs. Abraham Hyman, on "Urological Diseases in Childhood," and Dr. Abraham A. Brill, on "Psychoanalysis in Relation to Functional Genito-Urinary Disorders."—Drs. George W. Holmes, Boston, and Kenneth R. McAlpin addressed the New York Roentgen Society, January 19, on "Problems in Diagnosis and Treatment of Lymphoblastoma" and "Radiotherapy in Lymphoma," respectively.—Dr. Frank M. Frankfeldt, among others, addressed the Bronx County Medical Society, January 21, on "Some Common Rectal Disorders: Newer Considerations and Treatment."—Dr. William F. Cunningham addressed the New York Surgical Society, January 28, on "Partial and Subtotal Gastric Excision."—Dr. Robert T. Frank presented a paper on "Endocrine Diseases: Their Diagnosis and Therapy," before the New York Academy of Medicine, February 5.—Dr. Thomas J. Harris was elected president of the New York Physicians Mutual Aid Association recently, and Dr. Alfred C. Prentice, secretary. The association is in its sixty-third year.

NORTH CAROLINA

Name Duke Hospital Wards—Fourteen wards in the new Duke Hospital, Durham, were named after men prominent in medical history. Medical wards were named for Drs. William H. Welch of Baltimore, Sir William Osler, John Clark Nott of South Carolina, Daniel Drake of Kentucky, and Walter Reed of Virginia, surgical wards, William S. Halsted of Maryland, Edmund C. F. Strudwick of North Carolina, Crawford W. Long of Georgia, Ephraim McDowell of Kentucky, and James L. Cabell of Virginia, obstetric wards, J. Marion Sims of South Carolina, Francis Prevost of Louisiana, and Henry F. Campbell of Georgia, pediatric ward, John Howard of Maryland.

NORTH DAKOTA

Bill Introduced—S 79 to amend the pharmacy practice act with respect to the substances which may be sold by general dealers proposes to allow general dealers to sell proprietary medicines in original packages and such simple household remedies as may from time to time be approved for such sale by the state board of pharmacy.

Meningitis at State Training School—In an account of the occurrence of cerebrospinal meningitis in the state training school at Mandan in THE JOURNAL, January 31, page 5, it was erroneously stated that sixty-nine cases had occurred.

the school. The sixty-nine cases is approximately the number that occurred in the entire state during 1930. According to the state department of health, only eight cases occurred at the Mandan institution in two years.

OHIO

Bills Introduced—S 45 proposes to require the annual vaccination of all dogs against rabies. S 51 proposes to regulate the practice of cosmetology. S 58 proposes to exempt from the provisions of the medical practice act "persons treating human ailments by prayer or who only practice religious tenets of their church, if no material medicine, manipulation or material means are prescribed or used, is an exercise or enjoyment of religious freedom provided that the laws rules and regulations relating to communicable diseases and sanitary matters are not violated."

OKLAHOMA

Personal—Dr George N. Bilby, Alva, was appointed state health commissioner January 13, by Gov. W. H. Murray. He succeeds Dr. Clyde W. Beson.

Bills Introduced—H 23 proposes to create a board of barber examiners and to regulate the practice of barbering. H 38 proposes to provide that any person not residing within an incorporated city, who shall state under oath to any physician in the county in which he resides that he is not able to pay for medical services shall receive such medical aid as the physician deems necessary. The physician shall be paid one-half of the legal fee for such services rendered from a fund of \$38,500, which is appropriated by the bill.

OREGON

Bill Introduced—S 103 requires all applicants for licenses to practice any form of the healing art to pass an examination, to be given by the state board of higher education, in anatomy, physiology, pathology, chemistry and hygiene before presenting themselves for examination by their respective professional or cult boards.

Society News—The Oregon Pathological Society was recently organized by pathologists of the state medical society. Officers are Drs. Frank R. Menne, president, William M. Wilson, vice president, and Warren C. Hunter, Portland, secretary-treasurer. Meetings are to be held the second Monday in each month at the University of Oregon Medical School.—Dr. Ernest A. Woods, Ashland, discussed "Vision and Color Perception" at the Jackson County Medical Society, Ashland, Oct. 16, 1930.—Dr. Carl Henry Davis, Milwaukie, addressed the Portland Academy of Medicine, Dec. 11, 1930, on "Leukorrhea—A Neglected Symptom."—Dr. Horace J. Whitacre, Tacoma, addressed the Portland City and County Medical Society, January 9, on "The Financial Problem of the Wage-Earner in Illness."

PENNSYLVANIA

License Revoked—The state board of medical education and licensure revoked the license to practice medicine in Pennsylvania of Dr. Frederick J. E. Sperling, Wilkes-Barre, January 30, because of his conviction in the county courts of having performed a criminal abortion.

Society News—The twenty-third annual session of the Pennsylvania Conference on Social Welfare will open at Reading, February 25. Drs. Kendall Emerson, New York, and James Allen Jackson, Danville, among others, will speak on "Recent Progress in the Public Health Field" and "Role of Mental Hygiene in the Promotion of Mental Health," respectively.

Bills Introduced—S 33 provides that in certain counties where the fines, penalties and moneys collected from forfeited recognizances are paid into the county treasury, one-half of such sums shall be appropriated to such hospitals within the county as are entitled to receive state aid. S 34 proposes to authorize any borough to appropriate money for the support of any hospital which is engaged in charitable work and extends medical attention to residents of such borough.

Philadelphia

Personal—Dr. Rufus B. Weaver celebrated his ninetieth birthday January 10, with an informal reception at the Hahnemann Hospital, where he is a patient. Dr. Weaver was a teacher at Hahnemann Medical College for fifty-five years. In 1909 he received the first honorary fellowship of the Phila-

delphia Academy of Medicine, in recognition of work in anatomy.

Society News—Dr. George P. Muller, president of the Philadelphia County Medical Society, was elected president of the Health League of Philadelphia at a recent meeting.—The Philadelphia County Medical Society conducted its annual "Heart Night," February 11. Dr. Alexander Lambert, New York, spoke on "Sudden Death and Cardiac Pain," and Dr. Harlow Brooks, New York, gave an informal talk on "Angina Pectoris."—Dr. Damon B. Pfeiffer was the speaker, February 6, at the postgraduate seminar under the auspices of the Philadelphia County Medical Society on cancer of the lower bowel.—Drs. Alexander Randall and Karl Kornblum spoke on intravenous urography, and Dr. Charles H. Frazier on "Technic for an Operation for Blepharospasm," before the Philadelphia Academy of Surgery, February 2.—Dr. Arthur I. Wagers addressed the Philadelphia Laryngological Society, February 3, on prevention of acute surgical mastoiditis.—Dr. William J. Merle Scott, Rochester, N. Y., delivered the twenty-fifth Mary Scott Newbold lecture at the College of Physicians of Philadelphia, on sympathetic activity in diseases of the peripheral circulation.—Dr. Jesse O. Arnold, among others, addressed the Obstetrical Society of Philadelphia, February 5, on "Fluid Balance in the Treatment of Eclampsia."

SOUTH CAROLINA

Bills Introduced—H 117 proposes to provide that before a marriage license may issue the male applicant must submit a certificate of a reputable physician stating that the male party is free from all venereal diseases at a time not more than ten days prior to the date of such application. H 170 proposes to regulate the practice of barbering, which includes "the removal of superfluous hairs, warts, moles, or other blemishes from the scalp, face, neck or upper part of the body."

SOUTH DAKOTA

Illegal Practitioner Fined—Carol Irwin, Sioux Falls, is reported to have pleaded guilty recently to the charge of practicing medicine without a license and was fined \$50. This person is a white woman known locally as an "Indian herb doctor." The case was prosecuted by Messrs. Wall and Conaway, assistant state's attorneys. Dr. Carl William Forsberg, Sioux Falls, testified for the state.

Bills Introduced—H 33 proposes to repeal that law which provides that in a levy or execution on a judgment for a physician's bill no exemption can be claimed except absolute exemptions and household and kitchen furniture. An absolute exemption is stated by the present law to include family pictures, pew or burial lots, family bible and books, and wearing apparel. H 96 requires all pharmacies to be registered with the board of pharmacy and to require all pharmacies to be owned by licensed pharmacists.

TENNESSEE

Society News—The new full time health unit of Maury County started functioning, January 1, with Dr. Hannan C. Busby as director. It was made possible by the county court appropriating \$3,500, the city of Columbia, \$1,500 and the state \$5,000, an annual total of \$10,000.—Dr. Henry B. Gotten addressed the Memphis and Shelby County Medical Society, Dec. 2, 1930, on malignant tumors of the small intestine, and Dr. William Battle Malone, on chronic cystic mastitis.

Bill Introduced—H 514 proposes to accord liens to hospitals, physicians, surgeons and nurses, performing services for persons who have suffered personal injury, on any settlements or judgments obtained by reason of the injuries. Such a lien, however, shall not attach to any recovery or settlement had by reason of the workmen's compensation act. A physician, surgeon or nurse refusing or failing, when requested to do so by the injured person or his representative, to testify as to all relevant facts of the case within his or her knowledge shall not be entitled to the lien.

TEXAS

Bills Introduced—S 103 proposes to direct the state board of health to cooperate with the United States Public Health Service in eradicating malaria in Texas, and to appropriate \$50,000 for that purpose. H 96 proposes to provide that only a store in which a registered pharmacist is employed, and which conforms to the provisions of the pharmacy act, may be designated and advertised as a pharmacy or drug store.

UTAH

Bill Introduced—S 21 proposes to regulate the practice of chiroprody, defined as "the examination, diagnosis or treatment medically, mechanically or surgically, of the ailments of the human foot and massage in connection therewith, in all cases except the amputation of the toes or foot or the use of anesthetics other than local"

WASHINGTON

Bills Introduced—S 95 proposes to enact a new law regulating the possession, sale, prescribing or dispensing of narcotic drugs. H 145 seeks to amend the workmen's compensation act so as to permit osteopaths, chiropractors and other drugless healers to render the required medical attention to injured employees

Society News—Dr. Waltman Walters, Rochester, Minn., delivered four addresses as the guest of the Seattle Surgical Society at its annual clinics, February 6-7. Dr. Walters' subjects were "Evaluation of Various Gastric Operations," "Indications for and Results of Conservative Operations on the Kidneys," "Solution of Certain Problems of the Gastro-Intestinal and Genito-Urinary Tracts," and "Obstructive Jaundice. A Clinical and Experimental Study of Its Surgical Aspects."—Drs. Wilfred A. Ash and Maurice F. Dwyer addressed the King County Medical Society, February 2, on "Medical Aspects of High Intestinal Obstruction" and "Clinical and X-Ray Study of Gastric Tumors," respectively

WISCONSIN

Bills Introduced—S 58 proposes to constitute the state health officer, the secretary of the board of medical examiners, and the attorney general an ex officio state medical grievance committee to investigate, hear, and act on practices by persons licensed to practice medicine and surgery that are inimical to the public health. This committee shall have power to warn, to reprimand and to institute criminal actions or actions to revoke licenses. A 39, to amend the workmen's compensation act, proposes that when an employee during the term of his employment discovers that he has a hernia such fact shall be prima facie evidence that such hernia developed during the course of the employment

Society News—Drs. John B. Wear, Madison, and Drexel L. Dawson, Rice Lake, addressed the Barron-Washburn-Sawyer-Burnett County Medical Society at Cumberland, Dec. 2, 1930, on 'Renal Infection' and 'Spinal Anesthesia' respectively.—Dr. Frederick J. Gaenslen, Milwaukee, gave an illustrated address on 'Injuries and Diseases of the Knee Joint' before the Brown-Kewaunee County Medical Society, Green Bay, Nov. 25, 1930.—Dr. William F. Lorenz, Madison, among others, addressed the Grant County Medical Society at Lancaster, Nov. 25, 1930, on "Clinical Applications of Cerebrospinal Fluid Findings."—Dr. Ira R. Sisk, Madison, addressed the La Crosse County Medical Society, Nov. 18, 1930, on "Management of the Patient with Hypertrophy of the Prostate Gland."—Drs. Eben J. Carey, Milwaukee, and Hugh Cabot, Rochester, Minn., addressed the Milwaukee Academy of Medicine, Dec. 9, 1930, on 'Etiology of Pathologic Bone Growth' and 'What Constitutes Real Conservative Surgery of the Kidney,' respectively. Dr. Richard J. Muenzner addressed the academy, Dec. 10, 1930, among others on 'Cavernous Sinus Thrombosis with Recovery.'—Dr. Elven J. Berkhiser, Chicago, addressed the Outagamie County Medical Society, Appleton, January 15, on infantile paralysis.—Dr. Francis D. Murphy, among others, addressed the Medical Society of Milwaukee County, January 9, on complications of diabetes mellitus.—The Dane County Medical Society was addressed, January 22, at Madison by Drs. Frank F. Bowman on 'City Health Program for Diagnosis and Management of Pulmonary Tuberculosis,' Harry M. Guilford, 'Incidence of Tubercular Malaria and Undulant Fever,' and William D. Stovall, 'Value of Laboratory Methods for Diagnosis of Whooping Cough.'—Dr. Elmer L. Severinghaus, Madison, addressed the Marathon County Medical Society, January 15, on 'Menopausal Disturbances and Hypertension.'

WYOMING

Bills Introduced—S 32 proposes to create a board of barber examiners and to regulate the practice of barbering. S 37 proposes to impose a penalty for practicing medicine, surgery or obstetrics without first having received and recorded with the county clerk of the county in which the licensee practices a certificate from the state board of medical examiners. H 82 proposes to except from the provisions of the

medical practice act "persons treating human ailments by prayer or spiritual means, as an exercise or enjoyment of religious freedom, and provided, further, that the laws, rules and regulations relating to communicable diseases and sanitary matters are not violated"

GENERAL

Unauthorized Solicitor—R. J. Thomas, aged 37, height 5 feet 10 inches, with auburn hair and hazel eyes, is not an accredited agent of the American Medical Association. Authorized solicitors carry credentials signed by Dr. Olm West, Secretary and General Manager of the Association

Medical Relief in the Drought Area—A conference of health officers in the drought area was called by Dr. Hugh S. Cumming, surgeon general of the U. S. Public Health Service, for February 10, at Memphis, Tenn. The purpose was to make a survey of health conditions and to ascertain what steps might be necessary in the purchase and distribution of medical supplies for these areas, as provided in a deficiency bill passed by Congress appropriating \$2,000,000 for the work

New Instruments for Old—Recently a young man carrying a bag of cystoscopes and a Wappler catalogue, called on Dr. Herman L. Kretschmer, Chicago, and failing to complete a sale, offered to exchange some new cystoscopes for old ones and the difference in price. Dr. Kretschmer selected two cystoscopes from the catalogue and gave the young man four old ones and agreed to pay \$88 on the delivery of the new instruments. After waiting a few months, Dr. Kretschmer wrote the Wappler company. In reply he was told that they had no such representative on the road

Entrance Requirements at University of Vienna—The dean of the Medical Faculty of the University of Vienna, Austria, has notified the American ministry at Vienna that American citizens who file application to become regular students in the medical department must have the degree of bachelor of science or bachelor of arts. In addition, prospective students must comply with the minimum American requirement that is, twelve hours of chemistry, eight hours of biology and eight hours of physics. They must also take in Vienna a part of the examination (rigorosum) in anatomy, histology and physiology

Report of National Leprosarium—Twenty-three patients were released from the National Leper Home, Carville, La., during the year ended June 30, 1930, the annual report to the U. S. Public Health Service shows. Eight additional patients were eligible for parole, but because of their disfigurement elected to remain at the hospital. Fifty-five new patients were admitted and twenty-two died. Of 308 under treatment 163 were receiving chaulmoogra oil by mouth and 120 were receiving intramuscular injections of benzocaine chaulmoogra oil. Approximately twenty are permanently maimed. In the neuro-psychiatric service forty-five new patients and seventy-nine old patients were examined and advised concerning neurologic manifestations. Seven were confined to the psychopathic ward. Experimental work including the use of various drugs in the treatment of leprosy, treatment of nasal lesions in the hope of preventing involvement of the eyes, administration of mesterol in orthopedic cases and roentgenologic study of bone changes are discussed in the report

Medical Bills in Congress—H. R. 16591 introduced by Representative Leach, Pennsylvania, proposes the erection of a veterans hospital at or near Creson, Cumberland County, Pa. H. R. 16620 introduced (by request) by Representative Johnson, South Dakota, proposes among other things to make it mandatory that hospitalization and outpatient and dispensary treatment be recorded all veterans disabled from any cause. H. R. 16658 introduced (by request) by Representative James, Michigan, proposes to authorize the construction of additional hospital facilities at the various branches of the 'Bureau of National Homes.' H. R. 16659 introduced (by request) by Representative Johnson, South Dakota, proposes to establish a permanent medical service in the United States Veterans Bureau. H. R. 16693 introduced by Representative Wood, Indiana, proposes that the Administrator of Veterans Affairs be authorized to purchase the West Baden Springs Hotel, West Baden, Ind., for the hospitalization of veterans. H. R. 16702 introduced by Representative Foss, Massachusetts, proposes to authorize the enlargement and modernization of the veterans hospital at Rutland, Mass. H. R. 12169 has been favorably reported to the House proposing to define what constitutes the practice of naturopathy in the District of Columbia (Report No. 2432). S. 5959 introduced by Senator Walsh, Montana, proposes that the surgeon general of the public health

service be authorized to purchase from the state of Montana the state laboratory at Hamilton Mont constructed for the prevention, eradication and cure of spotted fever S 5961, introduced by Senator Hufield West Virginia proposes to provide federal aid to the several states in the care treatment education vocational guidance and placement and physical rehabilitation of crippled children S 255 the Jones maternity and infancy bill, has been reported with amendments to the House (Report 2485) It was amended in the House Committee on Interstate and Foreign Commerce by striking out all after the enacting clause and inserting the amended provisions of H R 12995, the Cooper Robison bill providing that the United States shall cooperate with the states in promoting the general health of the rural population as well as the welfare and hygiene of mothers and children H R 3594, providing for the deportation of aliens convicted of violating the Harrison Narcotic Act has been reported to the Senate without amendment (Report 1443) H R 9676 authorizing the Secretary of Navy to proceed with certain public works at the United States Naval Hospital Washington, D C has been reported to the Senate with amendment (Report 1436) H R 10166 has passed the Senate with amendments proposing the reconstruction of the Naval Hospital at Philadelphia S 5984, introduced by Senator Copper Kansas and H R 16777, introduced by Representative Zihlman Maryland propose to authorize the construction of a sanatorium for the District of Columbia for adult tuberculosis patients S 5986 introduced by Senator Wheeler Montana, proposes to make it mandatory that the Administrator of Veterans' Affairs furnish hospitalization for all veterans not dishonorably discharged without regard to the nature or origin of their disabilities and to create service origin presumptions for any chronic or constitutional disease which developed a 10 per cent degree of disability prior to Jan 1, 1925 S 6015, introduced by Senator Wagner, New York proposes to provide for the retirement of certain medical reserve officers of the United States Army Navy and Marine Corps S 6019, introduced (by request) by Senator Reed, Pennsylvania, proposes to amend the World War Veterans' Act to provide among other things, that the Administrator of Veterans' Affairs shall furnish hospitalization and outpatient and dispensary treatment to all veterans not dishonorably discharged without regard to the nature or origin of their disabilities S 6020 introduced (by request) by Senator Reed Pennsylvania, proposes to establish permanent medical service in the United States Veterans' Bureau H R 16782, introduced by Representative Smith, Idaho proposes to authorize the erection of a veterans hospital at Lava Hot Springs, Idaho H R 16837, introduced by Representative Shott, West Virginia, proposes to provide for federal cooperation with the several states in the care, treatment education vocational guidance and placement, and physical rehabilitation of crippled children H R 16854, introduced by Representative Douglas, Arizona, proposes to provide for the erection of an addition to the veterans' hospital at Tucson Ariz H R 16853 introduced by Representative Douglas, Arizona proposes to authorize the erection of an addition to the veterans hospital at Whipple, Arizona S 3344, a bill supplementing the National Prohibition Act for the District of Columbia was considered by the Senate during the week beginning February 2 An amendment to the bill proposed by Senator Hawes Missouri, which would have removed in the District of Columbia the restrictions imposed by the National Prohibition Act on physicians with respect to the prescribing of vinous and spirituous liquor, was defeated by a vote of 45 to 25

MEXICO

Mexico Limits Influx of Foreign Physicians—The secretary of the interior of the Republic of Mexico has issued instructions to the department of immigration to the effect that foreign physicians will not be permitted to enter the country to practice unless they have previously been authorized to do so by the department of the interior These instructions were based on a recommendation from the department of public health which pointed out that many of the foreign physicians coming to Mexico to practice do so under false claims having received their certificates of graduation in medicine either from a diploma mill or having obtained it otherwise by irregular means Some practice under their second name when it happens to be the same as the last name of a widely known physician The department of public health has received complaints from victims of foreign quacks An additional reason for restricting the immigration of foreign physicians is the severe economic condition of Mexican physicians and the fact that the influx of foreign physicians makes worse the economic situation of the physicians

The Most Significant Relic of Primitive Man

At University College, Prof G Elliot Smith gave a lecture on the Peking man, with the Chinese minister presiding He described the cranium found in the limestone cave near Peiping, Dec 2, 1929, as the most significant and illuminating relic of primitive man ever recovered Its characters established a bond of union between the other two types of early man comparable in age, *Pithecanthropus* of Java and *Eoanthropus* of Piltdown, England, which before this discovery seemed to be irreconcilable with each other and were both regarded with doubt The finding of *Sinanthropus* was important not only for the intrinsic evidence it provided but also because it conferred respectability on the other two The investigations in China had established confidence in the other two genera and destroyed doubts regarding their nature and significance The evidence of the geological age of the Peking man—the early Pleistocene—was more certain than that of the other two for the remains were found on the spot where their original owners left them when they died in the cave The vast collection of animal bones which had been carefully studied, belonged to creatures contemporaneous with Peking man They had been studied by many competent paleontologists who agreed that they referred to an epoch more recent than the Pliocene This could not be translated with certainty into figures of years, but Prof A W Grabau of Peiping University believed that the changes in the radioactive elements in early Pleistocene rocks suggested 1 000 000 years Whether or not the Peking man was older than the fossils of Java and Piltdown there was no doubt that he represented a more primitive type His characters were more generalized some being distinctly reminiscent of man's simian ancestry and others foreshadowing qualities regarded as distinctive of *Homo sapiens* They made it easier to picture the original characters of the human family by revealing a type which, though human was curiously apelike and obviously close to the main line of descent of modern man In spite of the thoroughness of the investigation, eminent paleontologists were making erroneous statements In France and Germany they were claiming already that Peking man belonged to the genus *Pithecanthropus* in America that he was a Far Eastern example of Neanderthal man, and others again that the Chinese fossils were not human Having just made a careful examination of the remains on his visit to China and compared them with human and simian skulls, Prof Elliot Smith confidently supported the claim of the Canadian anatomist Dr Davidson Black that *Sinanthropus* was a member of the human family who revealed in every quality of his skull evidence to distinguish him from all known human types and to justify the separate generic rank suggested to define his status

The Centenary of James Maxwell

The University of Cambridge, October 1 and 2, will celebrate the birth of James Clerk Maxwell who, after Newton, may be regarded as the greatest scientific genius of Britain He was the founder of the great school of experimental physics in Cambridge He died at 49, before the world appreciated his genius During his short life he translated the results of Faraday's experimental work into exact mathematical form and laid the foundations of general electromagnetic theory by his treatise on electricity and magnetism His discovery of the electromagnetic nature of light led directly to the development by later workers of wireless communications, while his name is forever linked with the fundamental laws of the theory of gases Addresses will be given at the celebration by great con

temporary scientists—Einstein, Langmuir, Larmor, Planck, Jeans and J. J. Thomson. Maxwell's connection with Faraday makes it appropriate that his centenary should follow the September celebration in London of the centenary of Faraday's discovery of electromagnetic induction.

Altering the Constitution of the Royal College of Surgeons

There are about 2,000 fellows of the Royal College of Surgeons and 18,000 members. The fellows pass a higher examination in surgery and are designated FRCS. They are surgeons in the full sense of the term and generally are members of hospital staffs. Many of them practice only surgery or one of its special branches. They include all who are eminent in English surgery. The members pass a lower examination devised for those who will engage in general practice, and are designated MRCS. They usually practice surgery only in a minor form, their working being mainly medical. The college is governed by the council, which is elected from and by the fellows. The only occasion on which the members have an opportunity to say anything as to the government of the college is the annual meeting of members and fellows, when they can bring forward resolutions, which are submitted to the council. At this meeting they have for forty-two years passed a resolution that the members should be given the power to elect representatives on the council. This the council has always refused. At the 1929 meeting the members were twitted by the president, Lord Moynihan, with the fact that the number who attended was small (about fifty) and that he always saw the same faces. There was therefore no evidence that representation was desired by the members at large. At the 1930 meeting, which recently took place, the members demanding representation replied by bringing forward the result of a poll taken by postcard in Great Britain and the Irish Free State. This showed that for 12,766 cards sent out 6,832 votes were received in favor of representation and only 156 against. At the meeting, much was made of this, the argument was the "justice" of the claim for representation of nine tenths of the college roll and the need to protect the members against unqualified practitioners. The last argument shows a desire to bring the college into medical politics and to engage in work already fully performed by the British Medical Association. When a vote was taken, the request for representation was carried by 43 votes to 1. The president said in reply that the question of representation of the members had always been regarded by the council as of the gravest importance and that a special meeting would be held to consider the resolution. At this meeting the council adopted the following resolution:

The main functions of the college are to promote and encourage the art and science of surgery for the common weal and for this purpose to conduct the examinations of the college and to maintain the great museum and library placed under its care. In carrying out these functions the council organizes lectures and demonstrations, provides facilities for and encourages research, fosters social intercourse and the amenities of the profession and in every way possible renders the college an instrument for the advancement of surgery in its widest sense not only for the benefit of the members and fellows but the whole profession throughout the empire. In the opinion of the council these functions are well carried out under the present constitution after further and prolonged deliberation the council has therefore decided that it is not desirable to alter the constitution of the college by providing for the direct and separate representation of members of the college upon the council. The decision of the council is in conformity with the opinion expressed three years ago by the body of fellows of the college who are the electorate.

Though the agitation of the members for representation on the council has been carried on for forty-two years and has received some support in the medical press the decision of the council is right. Its claim that the functions of the college are well carried out under the present constitution is abundantly proved and has never been questioned. The handful of politically minded members who carry on the agitation has never been able to suggest any fault in this respect or indeed shown any interest in the functions. The members have not the competence of the fellows for the government of the college for they are not

surgeons in the important sense of the term but general practitioners. One of the objections of the agitators, as revealed at the annual meetings, is to drag the college into medical politics. This would be a descent from its proper sphere, which is purely scientific. It maintains the greatest pathologic museum in the world, which is a development of the collection made by the "father of scientific surgery," John Hunter. It is the home of English surgery. It does everything possible for the advancement of surgery. It maintains also a library and laboratories for research, in the highest degree of efficiency, and organizes lectures by all who are contributing to the advance of surgery. The conservator of the museum is Sir Arthur Keith, who is famous as anatomist, physiologist, pathologist and anthropologist. It is to be hoped that the control of this great college will remain in the hands of "surgeons," without any intrusion of those inspired by motives which have nothing to do with the advancement of surgery.

Attack on the Law Concerning Abortion

Dr. Julius Wolf, professor of political science, launched an attack recently on section 218 of the penal code, which pertains to abortion, in a work entitled *Mutter oder Embryo*. He advances arguments to prove that the present law is a survival of barbarism, emphasizing the misery of the woman who becomes a mother against her will, and the great suffering caused by abortion brought about by charlatans. With passionate zeal he takes up the cudgels against all those (ethicists, religious jurists, physicians) who approve all kinds of modifications and exceptions but who support the law imposing penalties on abortion. He urges that the civil state has not recognized that the care of the child is the correlate of the duty to give it birth or at least that it has not fully grasped the significance of the fact. Per se, Wolf is an opponent of abortion for he does not fail to recognize, nor does he minimize, its moral and physical dangers. He, too, gives prophylaxis the preference. But in addition to the medical indications stated in the draft of the penal code, he recommends making the interruption of pregnancy permissible, on request of the gravida, within the first three months of pregnancy if the capacity of the gravida to bear children is reduced, if offspring is undesirable for eugenic reasons, or if financial conditions constitute a contraindication to birth. If such abortions are then carried out according to the best scientific knowledge he contends that that will be a victory for hygiene no less valuable than other attainments of which it may boast.

The majority of physicians in whose hands the interruption of pregnancy lies for the most part (and should lie to a much greater extent) have been unable to accustom themselves to the idea that they should carry out any important intervention for other than medical reasons. As medical reasons they consider the risks affecting the health of the gravida and in this connection they attach a certain amount of importance to economic conditions, since with identical risks the health of a gravida in poor circumstances might be endangered whereas the conditions that obtained would constitute no menace to a woman with adequate means.

It has been pointed out, however, that this so-called official attitude of the *Deutscher Aerztetag* (THEIR JOURNAL July 19 1930 page 216) does not necessarily coincide with that of the majority of the individual physicians. In this connection the results of an inquiry instituted among the physicians of Hamburg are of interest. Of 1,266 questionnaires sent out replies were received to 880. Of this number only 41 expressed themselves in favor of permitting any physician to perform an abortion. 25 would accord such permission only to certain clinical cases. The purely social indications for abortion were approved by 359 and opposed by 517.

The attitude of women physicians toward the question is naturally of great importance. Several months ago, 356 women physicians of Berlin made far reaching demands resembling those of Professor Wolf. Soon afterward an opposing manifesto was issued by another group of women physicians. Recently, the League of German Women Physicians discussed the subject. Women physicians belonging to widely different groups expressed their views. Physicians with experience in German consultation centers on marriage and sex matters and physicians from Russia, gave their opinions. That the present situation for women is beset with many difficulties was admitted by all the speakers and also during the general discussion that followed. The need of providing adequate care for the married and for the unmarried mother was emphasized. The need of a reasonable birth control was universally admitted. However, no definite decision was reached with reference to section 218 of the penal code, pertaining to abortion.

Treatment of Disorders of the Feet

The Deutsche orthopädische Gesellschaft has established criteria for the treatment of disorders of the feet, the purpose being to oppose invasions of medical fields by the administration of sick benefit funds. Therein it is rightly emphasized that only the physician can decide whether in a given case of foot or leg disorder, any treatment is indicated. Therefore, the procuring of inlays from administration officials of the sick benefit funds, surgical supply houses, or shoe stores, without consulting a physician is disapproved. In many cases it is a waste of money, causes dissatisfaction in the minds of patients and not infrequently damages them directly, since the existing disorders are accentuated or serious disorders are overlooked and neglected. In most cases of disorders of the feet an inlay made especially for the patient is absolutely required, just as every eye patient needs a particular lens. The procuring of an individual inlay is, however, the prerogative of the orthopedic specialist. For the majority of foot patients a so called "normal inlay" does not exist, because of the great individual differences in the shape of the feet and in the nature of disorders of the feet. The fitting of individual measurements for an inlay, by means of a plaster-of-paris mold or some other scientific method, is the affair of a specialist and must be done personally by the specialist or must at least be supervised by him directly, and must be paid for as the performance of a physician. Likewise, the fitting of an inlay furnished by a surgical supply house is the affair of a specialist.

The Psychology of the Political Criminal

In times of political unrest, such as are now being experienced, political crime flourishes, and passions and instincts that possibly would have otherwise found a different outlet seek expression in this field. In a recent address, Professor Hubner, psychiatrist of Bonn and director of the university clinic for mental diseases, gave some information on the psychology of the political criminal, basing his statements on some eighty cases dating from the period 1914-1930, the greater portion of which concerned treason and the lesser portion espionage. In this connection he described various types of spies—the cavalier spy—natures that feel a need of expressing themselves and have an uncontrollable fondness of adventure who, as a rule, are not influenced by the greed of gain, natural swindlers, who are driven to take up espionage by a desire for gain, and the passive, unsteady natures, who are sought out by the opponent and are utilized for his purposes. Many hysterics or cyclothymics are induced by a certain fondness for boasting to betray secrets they have learned of by chance—without thinking of the fact that the act is punishable by law. Among these types, alcoholism and morphinism play a big part. Professional spies are nearly all caught, and either commit suicide or receive severe penalties. Most of them never settle down to a regular life. Among the types of revolutionists those who furnish the brains for the enterprises stay always in the background and thus rarely incur any great danger. Such

organizers and promoters are cool, calculating, conscienceless personalities, highly sensitive and possessing a high self esteem, who display great shrewdness in choosing their tools for the execution of their plans. Among these are the propagandists possessed of certain powers of oratory, together with considerable histrionic talent—persons who are fond of being in the forefront and who exert no slight influence over the masses. They are not always persons of high intelligence, and they present only in part ideas of their own, they are often lacking in critical judgment and, as a rule, do not maintain their position long. But the propagandists who have the capacity and the inclination to put their words into action take a definite stand for their political convictions, though they know that their influence will be of limited duration and that they are doomed to meet disaster. They are impetuous natures that shun no personal danger and that win temporary success through inspiring fear in their milieu. Another less common type of revolutionist are the fantastic world reformers—often dreamers unable to distinguish the feasible from the impossible. They are egoistic, petty and revengeful characters that do not maintain themselves long as leaders. Also the discontented and complaining types, which desire a change in conditions but usually do not possess the capacity of creating anything new, quickly pass off the stage. The last group is composed of submissive conformers, among whom there are many persons greedy of gain who have been raised to a position of prominence by chance. Their goal is not political and they readily assent to the opinions of the ruling majority until they have achieved their aim or have been forced by conditions to comply. Among the subjects examined by Hubner there were alcoholists, morphine addicts, imbeciles, epileptics, hysterics and schizophrenics. The most dangerous types are the "gustige urheber," or persons with an impelling desire to launch something new and startling, and the "propagandisten der tat," propagandists who insist on expressing their views by energetic and oftentimes violent action.

ITALY

(From Our Regular Correspondent)

Dec. 15, 1930

Congress of Industrial Medicine

The ninth Congresso nazionale di medicina del lavoro was held recently in Rome, at the Istituto di patologia medica del Policlinico. Professor Devoto of the University of Milan, in his inaugural address, after summarizing the most recent manifestations concerning the pathology of labor, emphasized the importance of the topic to be discussed. "The Problem of the Respiratory Pathology of Dusts."

RESPIRATORY DISEASE AND DUST

The discussion of the first topic, "Respiratory Diseases Due to Dusts," was divided into several parts, each assigned to a different speaker. Professor Caccari of Naples, who discussed part I, on the etiology and pathogenesis of respiratory diseases due to dusts, pointed out that, with the progress of social legislation and with the extension of insurance against disease, this group of disorders would certainly be included among the diseases for which compensation can be claimed under the workmen's compensation act. It is advisable, therefore, to collect in advance all information necessary to facilitate the work of the physicians who are called on to decide on the relations between a pathologic condition and the mode of employment, and hence admit or deny the compensability. According to the speaker, the term "pneumoconiosis" should be restricted to cases of pulmonary fibrosis, while all the other respiratory disorders that are due to dusts and are strictly associated with the work in which the workman is engaged should be designated respiratory diseases due to dusts. It seems advisable to divide dusts into two groups, according as the action is mechanical or chemical. Many classes (workers in tobacco, cotton, hemp, flour, cement, ceramic products) are frequently subject

to bronchitis. True types of pneumoconiosis are encountered among those who work in surroundings where there is siliceous dust, whether pure or mixed with other substances (miners of coal, granite, asbestos, gold, iron, stone cutters, workers in ceramics). Workers in hemp, linen, silk, furs, and the like, suffer frequently from bronchial asthma. Miners of cobalt develop frequently cancer of the lung. According to recent research, pulmonary anthracosis should not be considered as a disease, if the black pigment is pure carbon, without a trace of silica, it cannot provoke pulmonary sclerosis, it is, however, the cause of a morbid state and may give rise to pathologic changes of various kinds.

With respect to the manner in which the particles of dust permeate the various zones of the lung, it is necessary to take account not only of the lymph currents but also of the continual stretching that the lungs undergo during the respiratory acts. Often the patient does not complain of any disturbance and it is only the radiologic examination, together with the functional tests, that reveals the deviations from normal. Before subjective and objective disturbances can arise, the so called margin of safety must be exceeded, for, in general, it may be stated that there is an excess of pulmonary tissue. Some dusts provoke a state of general hypersensitivity, which affects more particularly the respiratory apparatus, giving rise to an asthmatic syndrome.

The paper on part II, concerning the pathologic anatomy and the clinical aspects of respiratory diseases due to inhalations of dust, was presented by Professor Coppa of Naples, who distinguished, among the disorders of the organs of respiration, due to inhalation of dust, diseases of the upper air passages, diseases of the trachea and the bronchi, and pulmonary diseases. For each group of disorders he described the means of defense employed by the organs of respiration and the pathogenesis of the lesions that develop. Nearly all these morbid types are of a chronic nature. One of the more grave lesions is chronic catarrhal rhinitis, which is frequent in all the classes of workmen who work in a dust laden atmosphere. This lesion is important, not only in itself but also because it induces a lessening of the means of defense available to the organism for the limitation of the invasion of dusts into the lower air passages. Other lesions characteristic of the nasal cavities are ulceration of the septum, found in workmen who come in contact with dusts of chromates and also in cement workers. The inhalation of calcium dust gives rise to burns of the oral cavity, which, though slight are painful. The bronchial disorders are rather more important than those of the pharynx and of the larynx. The most harmful for the bronchi are the siliceous dusts. Among sulphate workers, textile workers and the like stubborn chronic bronchitis is found and in the sputum it is easy to discover, without the aid of the microscope the characteristic elements of the inhaled dust. Sometimes the sputum has a characteristic color, being black among the coal miners, pinkish among those who inhale the dust of iron oxide and grayish or bluish in sulphate workers. Among the pulmonary disorders due to dusts the chronic forms have occupational characteristics. The speaker suggested dividing them into three large groups: (1) pneumopathies due to dusts of local mechanical chemical action; (2) pneumopathies due to dusts of humoral action; (3) pneumopathies associated with tuberculosis, tumors or mycosis. The first group is the most numerous and the most important. To this class belong also the pneumoconioses. By pneumoconiosis is meant only chronic interstitial pneumonitis such as was described by Zenker and which is characterized by extensive processes of fibrosis with areas of atelectasis and emphysema and with production of cavities. Between the subjective disturbances and the results of the radiologic examination on one hand and the clinical examination there exists a notable disagreement that is absolutely typical of pneumoconiosis. The diagnosis of this morbid type is reached by ruling out above all tuberculosis and by

evaluating then all the anamnestic, environmental and individual data, with the aid of the radiologic examination and the examination of the sputum. The second group of pneumopathies, caused by dusts of a humoral action, includes the anaphylactic disorders of occupational origin, such as pollenosis and bronchial asthma. Often it is not easy to discover the hypersensitizing cause which may be the inhalation of the dust of cement, or porcelain and the like.

Dr Sgambati Pastena of Naples took up at this point the discussion of part III, radiologic research in pneumoconiosis. The speaker described the radiologic picture of pneumoconiosis, which varies according to the three stages of the morbid process. The first stage is characterized by an accentuation of the pulmonary design. There is an absence of clinical phenomena and subjective disturbances. In the second stage, there is observed a uniform punctate appearance of the pulmonary tissue, due to the presence of numerous small foci. The shadows of the hilus are enlarged. There is some evidence of dry localized pleuritis, and sometimes there is a slight emphysematous condition of the base. In this stage the subjective disturbances are slight and the clinical signs scarce. In the third stage one observes large roundish shadows, with rather clear outlines scattered over the pulmonary fields of varying size and localized chiefly in the middle areas. The apexes are nearly always immune. The pleuritic signs are more marked. Subjectively the disturbances in this stage are noteworthy, and the clinical signs are numerous but always disproportionate to the radiologic manifestations. The characteristic phenomena, from the radiologic point of view, for the diagnosis of pneumoconiosis are: aspect of the lungs resembling wet snow; symmetrical localization of the lesions, with prevalence in the middle portion of the pulmonary fields; apexes normal; apparent discrepancy between the radiologic manifestations and the clinical data. The differential radiologic diagnosis between pneumoconiosis, tuberculosis, tumors and pulmonary syphilis is often rather difficult and should be supplemented by clinical and laboratory data. The speaker closed his discussion by proposing the drafting of a resolution to be sent to the authorities in charge of industrial hygiene to the effect that all workmen admitted to dusty employments be obliged to furnish a recent genogram of their lungs. The adoption of this proposal (previously advanced by Tandoia and Karim-Marmucci, at the International Congress of Tuberculosis held in Rome with respect to the sons of tuberculous persons) would make it possible to admit to such industries only persons whose respiratory apparatus is sound. By repeating periodically the radiologic control it would be possible to detect a quiescent pneumoconiosis by the clinical signs before it could do serious damage to the health of the workmen.

Many conventionists took part in the discussion of the topic in hand. Professor Quarelli emphasized the need in every case of giving a radiologic examination. He brought out the importance of the intervention on the reticulo endothelial system of the lung in pneumoconiosis and referred to his recent researches on the behavior of cholesterol in asbestosis. In this disorder the speaker found diminution of the cholesterol content of the blood.

Professor Devoto while not denying the existence of positive radiologic pictures in cases of pulmonary silicosis without clinical symptoms declared them to be rather rare. He suggested that the congress should apply to the Consiglio nazionale delle ricerche to obtain the necessary aid to carry on extensive researches on pneumoconiosis due to sulphur. The studies should be done in Sicily where sulphur abounds and could be carried out at the Clinica medica in Catania which is under the direction of Professor Ferrarini.

Dr Turano asserted that the marble dust of Carrara is harmless and holds that it is incapable of producing changes in the respiratory apparatus.

Professor Ferrarini, in view of the importance that the sulphur industry has in national economics, considers it necessary to make a profound study of the diseases associated with the handling of sulphur.

Numerous unofficial communications were presented. Caiso of Naples considered the respiratory diseases of coal hewers. An inquiry made on 450 coal hewers, in the port of Naples, revealed that 85.5 per cent of them were affected with diseases of the respiratory apparatus, with a prevalence of diffuse bronchial catarrh (64.2 per cent). Caiso carried out spirometric researches on coal hewers and microscopic researches on their expectorations. He noted diminution of the respiratory capacity and the presence in the sputum of exfoliated cells mixed with particles of coal. Caiso explained his method of research for the chemical diagnosis of coal in intracotic pulmonary tissue. Pignatari found that, among workers in hemp, 70 per cent were affected with diffuse bronchial catarrh, 10 per cent with bronchial asthma and 20 per cent with apical sclerosis.

The communications having been presented, Professor Ranelletti spoke on the postgraduate school of industrial medicine, recently established at the University of Rome.

Milan was selected as the meeting place for the next congress, which will be held in 1932, since in 1931 an international congress will be held at Geneva. The topics on the program are: (1) the work of intellectuals, (2) work in the fields, and (3) the pathology of solvents.

BELGIUM

Jan. 3, 1931

The Congress of Occupational Medicine

The twenty-second *Congrès de médecine professionnelle*, held at Brussels, was well attended. There were three topics on the program, in the presentation of which the following conclusions were brought out:

THE EXCESS OF PHYSICIANS

There is an excess of physicians in parts of the country and it is feared that the same condition will exist in all the provinces. The congress passed a resolution to the effect that a committee, on the basis of the indications pointed out in the discussions, should inquire into the best means of remedying the condition, among others: (1) the recovery, for the benefit of the medical profession, of a number of special sources of income that have been allowed to slip gradually into the hands of persons not authorized to practice the art of healing, (2) an energetic movement, with the use of all possible recognized means, to induce more young Belgians to take up a colonial career.

SOCIAL INSURANCE

The *Fédération médicale belge*, which comprises nearly all the members of the medical profession in Belgium, intends to give its loyal support to the proposed system of social insurance, provided the insurance law does not interfere in any way with the free practice of medicine. Consequently, the twenty-second *Congrès de médecine professionnelle* trusts to the directing committee and to the *Commission des assurances sociales* to bring it about that the law as passed by parliament shall be in absolute conformity with the *charte médicale* unanimously adopted by the general assembly Dec. 8, 1929. It passed a resolution that all the articles of the *charte médicale* be officially endorsed by the law. The congress passed also the following resolutions: 1. Previous to the passage of the social insurance act the congress advocates the passage of the bill creating an ethical order of physicians the purpose of which is to protect the medical profession by reducing to a minimum the fears and the constant criticisms offered with reference to social insurance. 2. Medicine must retain its free and independent character and especially the role of the family physician which is in no wise incompatible with social medicine must not be impaired by

overstandardization, which takes the soul out of medicine. 3. Through the influence of the directing committee, and by all other means possible, the eight points approved by the *Fédération médicale belge*, with reference to the attitude of medicine toward social insurance, should become widely known and accepted. 4. The medical profession of Belgium, and particularly the young men, must be constantly enlightened in regard to the dangers that beset the profession.

THE ADMISSION OF PAY PATIENTS TO HOSPITALS OF THE PUBLIC WELFARE DEPARTMENT

The twenty-second *Congrès de médecine professionnelle*, after discussing the paper pertaining to the terms of admission for pay patients to hospitals of the public welfare department, declared that it appeared incompatible with the law in regard to public welfare that persons with adequate means should be admitted to the hospitals of the public welfare department, but that nevertheless it is ready to approve the granting of such admission in view of recent social developments, provided account is taken of the precise considerations announced to the senate by Senator Digneffe, that is to say, with regard to the free choice of physician and the payment of fees directly to the attending physician. The congress congratulated the committees of the *Assistance publique* that have already accepted this view, much to the satisfaction of all physicians, and urged the public authorities and the general public not to lose sight of the fact that, if this appeal of the physicians is rejected, it will signify the suppression, within a short time, of free medicine and the introduction of state medicine.

School Medicine

The *Comité d'entente franco belge* passed a resolution, based on a communication submitted by Mr. G. Rency, on the subject of overstudy in schools. The congress discussed the fact that there are no physicians among the members of the councils or secondary instruction in Belgium, and recommended that physicians be chosen on these councils, and in general, the extension of the role of the physician in instruction of all ranks or degrees. The congress suggested as a remedy for overstudy a division of the subject-matter and the sacrificing, where overstraining existed, of certain less important study material, in other cases, classes can carry the full load. The congress held that it would be well to distinguish carefully the class hours properly so called from the study hours—preferably under the control of the professor. If the study hours could be carefully controlled, it would bring considerable relief to the pupil. The congress cannot approve the complete suppression of study hours carried on outside the class, as such study is indispensable in several branches of learning, but the instructors should be careful about distributing the tasks of the pupil equitably over the different days of the week.

Mental Patients on Parole

New regulations concerning the discharge on parole of mental patients from institutions have been enacted. The physician, with the written consent of the authority or of the person that caused the internment, can permit the temporary removal of an inmate of an institution or his return to his family on parole. The names of inmates of institutions who are dismissed on parole will be entered by the physician in charge of the hospital in a special register and the competent prosecuting attorney will be immediately notified. Likewise the mayor of the town or commune in which the patient resides. Temporary discharge will become permanent after the lapse of three months unless, before the expiration of such time, the parole period has been prolonged. Such prolongation can be renewed before the expiration of any three months period, except that the total duration of the parole may in no case exceed one year. After the discharge has been declared final, reinternment in the hospital can be accomplished only by means of the usual legal commit-

ment The authorities who had been informed of the discharge on parole should be informed of any prolongation of the parole period or of the reinternment of the patient in the psychopathic hospital

The New Buildings of the University of Brussels

Stirring ceremonies marked the opening of the buildings erected at Solbosch with the aid of the C R B Educational Foundation, and on the boulevard de Waterloo with the help of the Rockefeller Foundation Delegations of Belgian and foreign universities brought to the University of Brussels evidences of the interest of the world of letters Addresses were delivered by J Servais, Rector G Smets, Professor Berthelemy and Minister Vauthier The king summarized the purpose of the ceremonies with these words 'Intellectual cooperation is a pacifying influence the importance of which must be recognized When based on disinterestedness it has an incontestable moral value, the influence of which, it is to be hoped, will be extended as we learn to appreciate its benefits The earnest occasion that has called us together, coming as it does after that celebrating, two years ago the inauguration of the new Louvain library (also under the auspices of our friends in America), acquires thus a special significance that the speakers who preceded me have so ably brought out'

At the inauguration of the School of Medicine, which was attended by the queen, Professor Bordet recalled the memory of Professor Deppe who secured through American philanthropy, these most generous gifts to the university

In well chosen words Mr Gibson, the ambassador of the United States, referred to the important part played by Mr Hoover and Mr Francqui in the creation of the C R B Educational Foundation He called attention also to the great figure of Dr Paul Heger Mr Kenyon's speech in the name of the British delegation and Mr Henri Pirenne's words in behalf of the other delegates were warmly applauded

The Medical Association of Katanga

Under the name of Cercle medical du Katanga an association that groups together as corporate members the doctors of medicine the veterinarians and the pharmacists resident in the province of Katanga to the number of about eighty has been formed This association, an affiliate of the Societe belge de medecine tropicale has been placed under the honorary presidency of Dr Trolli, chief physician of the colony The Cercle medical du Katanga, the headquarters of which is at Elisabethville, will hold monthly meetings of the members residing in the chief town of the province as well as any transients who may desire to attend for the purpose of discussing the questions of hygiene or medicine that have a bearing preferably on local activities and live problems

JAPAN

(From Our Regular Correspondent)

Dec 10 1930

Business Depression and the Hospitals

Since the business depression in this country the patients treated in hospitals have greatly decreased in number with the exception of those treated in charity hospitals During the first six months in 1930 the cases treated in the 150 hospitals in Tokyo amounted to about 303,000 which was a decrease of 154,000 in comparison with the number during the same period in 1929 There are nearly 150 vacant beds in the hospital attached to the medical department of the Tokyo Imperial University where there used to be no vacancy 180 beds are unoccupied in the hospital of the Keio Medical College And the number of outpatients has also fallen to as many as 0.4 per cent a day compared with that of 1929 in the latter hospital On the other hand all charity hospitals in Tokyo are now full of patients and some outpatients come as early as 4 o'clock in the morning The increase in the number of patients is so great that some of the charity hospitals have

had to increase the number of physicians For instance, in the Tsujin Charity Hospital from 250 to 400 more patients are treated every day And those patients free of charge in the hospitals do not like to leave the hospital even after recovery

Birth Control in Tokyo

In spite of strong opposition, the Tokyo authorities mainly through the efforts of the assistant mayor, Mr Shirakami, have kept the office for advice regarding birth control at Shiba in operation since January, 1930 It is reported that he has evolved a new plan of birth control for the benefit of the poor in the city With the aid of the physicians in the municipal hospitals in addition to Dr Mazima, member of the municipal assembly who has been to Europe investigating birth control, the authorities are going to give a course of lectures to municipal employees and social workers in each ward of the city Mr Shirakami intends to have them instruct 9,000 families suffering from the heavy burden of seven or more children with a small income to support them Dr Isoo Abe, one of the leaders of the social democrat party, is of the opinion that by this means the poor will be saved from the great difficulties now encountered in making a livelihood and that one of the problems of population and unemployment will be solved

Number of Physicians in Japan

The number of physicians in this country in 1930 is reported to be 48,804 43,676 of whom are engaged in practice which is 6.94 per 10,000 people The proportion of 15,573 dentists to 10,000 people is 2.31 that of 49,399 wet nurses is 7.69, and that of 18,366 pharmacists is 2.92 In comparison with the number year before last, that of doctors is increased by 944 and 2,791 new graduates are expected from medical colleges at the end of March

First Physical Training Celebration

Under the auspices of the Japan Physical Training Union the first celebration was held in Tokyo, Nov. 2 1930 during health week The ceremony was held in the parks of Hibuya and Ueno and the minister of education attended the latter which was begun at 9 o'clock in the morning During health week the educational ministry planned to broadcast lectures on physical training an address by Baron Yamakawa, chief of the physical culture section of the educational ministry, 'General Survey of Land Sports' by Mr Hirayama, chief of the Japan Physical Training Union Water Sports by Mr Suehiro professor at the Tokyo Imperial University Baseball Matches by Mr Ashida, chief of the Japan Baseball Union, and other addresses

Medical Meetings

The Local Governors Conference was held Oct. 10-11 1930 at the premier's residence and the topics discussed were home made medicines the control of narcotic drugs and extension of leprosariums Home made medicines have resulted from the economic depression Both the premier and the minister of the interior gave instructions that governors should make strict supervision lest opium be illegally sold or imported The extension of leprosariums was favored

The health committee met in the home ministry Nov. 26 1930 and the special committee studied and discussed the drafts of the laws for controlling parasites in farming villages and the laws for controlling the sale and use of birth control drugs and apparatus The documents were sent to the home minister after the conference

The conference of the central hygiene council met Dec. 8 1930 The topics discussed were the act for the prevention of parasitism the act for the enforcement of unitary corporation the amendment in the laws controlling the spread of infectious diseases and the act for the control of distribution of harmful drugs and apparatus for birth control The legislation will be acted on during the present session of the diet

Marriages

EDWARD FRANKEL, JR., New York to Miss MARIAN DINE de Villavilla y Tornes of Greenwich, Conn., January 24

L C COWEN, Rising Sun, Ind., to Mrs. Mittie Griffin of Artesia, Miss., in Miami, Fla., Dec. 9, 1930

JOHN TRIMBLE EADS, Philadelphia to Miss Elizabeth Jane Downs of Newark, N. J., Nov. 30, 1930

SAM LITZBERGER, Anderson Ind. to Miss Frances Louise Turner of Birdsboro, Pa., Nov. 29, 1930

HENRY W. BOPP, Terre Haute, Ind., to Miss Margaret Ruth Hutchens of Seymour, Dec. 26, 1930

HARRY C. BEATTY, North Longwood, N. Y., to Miss Agnes Hall of Calhoun, Ga., Nov. 30, 1930

JAMES W. DAVIS, Statesville, N. C., to Miss Nancy Smith of Greensboro, Dec. 10, 1930

RALPH J. GILMAN, Hartford, Conn. to Miss Ruby Weaver, in Tarrington Dec. 20, 1930

FRANK W. RATCLIFF, Kingman, Ind., to Miss Mary Holt in Chalmers Dec. 20, 1930

HUGH D. STEERS to Mrs. Ethel Morrison, both of Akedo, Ill., January 22

Deaths

John William Draper ☉ New York Medical Department of the University of the City of New York, 1898 member of the American College of Surgeons and the American Gastro-Enterological Association, formerly associate in surgery, Columbia University College of Physicians and Surgeons and associate in experimental surgery University and Bellevue Hospital Medical College director of the surgical research laboratory of the Mayo Clinic, Rochester Minn., 1909-1912, attending surgeon to the State Hospital for Insane, Trenton, N. J., and the Midtown Hospital New York, aged 59 died, January 26 in the Lower Hospital, following an operation on the gallbladder

Edwin Welles Dwight ☉ Boston Harvard University Medical School, Boston, 1891, formerly instructor of legal medicine and surgery at his alma mater, and professor of legal medicine, Tufts College Medical School on the staff of the Boston City Hospital, medical director of the New England Mutual Life Insurance Company, author of "Toxicology" and "Medical Jurisprudence", aged 67, died, January 14

David Harrison Rand, Portland, Ore., Willamette University Medical Department, Salem 1885, member of the Oregon State Medical Society city and county coroner, 1898-1902, for more than forty years on the staff of St. Vincent's Hospital, aged 69, died, Nov. 29, 1930, in San Francisco, of uremia

Willis E. Ford, Utica, N. Y. Medical Department of the University of the City of New York, 1872 member of the American Climatological and Clinical Association for many years on the staff of St. Luke's Hospital, aged 80, died, January 29, of bronchopneumonia and arteriosclerosis

Roy Blosser ☉ Providence, R. I., Atlanta College of Physicians and Surgeons 1902, Jefferson Medical College of Philadelphia, 1906, member of the New England Dermatological Society, served during the World War, aged 48, died, January 8 of illuminating gas poisoning

Thomas Ragan ☉ Shreveport, La., Medical Department of the Tulane University of Louisiana, New Orleans 1891 served during the World War member of the American College of Surgeons, aged 64, died January 9, of cerebral arteriosclerosis and cerebral edema

William Hayes Brosius, Mont Alto, Pa., Jefferson Medical College of Philadelphia 1886 member of the Medical Society of the State of Pennsylvania, aged 70 died Nov. 19, 1930 of chronic parenchymatous nephritis, hypertrophy of the prostate and chronic cystitis

James F. Lemon, Dansville Mich. University of Michigan Medical School Ann Arbor, 1882 formerly member of the state board of health for twenty-five years secretary of the school board, aged 76 died January 5, of diabetes mellitus

Charles D. McGettigan ☉ San Francisco Medical Department of the University of California, 1896 veteran of the

Spanish American War, aged 57, on the staff of St. Mary's Hospital, where he died, January 23, of influenza

Temple J. Smith, Jonesville, La., Maryland Medical College Baltimore, 1903 member of the Louisiana State Medical Society, aged 50, died, January 6, in the Natchez (Miss.) Sanatorium, of pneumonia, following influenza

William David Herring, Midlothian, Texas, Baylor University College of Medicine, Dallas, 1916 member of the State Medical Association of Texas, aged 48, died, January 1 in a sanatorium at Waco, Texas

Samuel McGaughey Indianapolis, Medical College of Indiana, Indianapolis 1900, served during the World War formerly county health commissioner and county coroner, aged 55 died, January 10 of heart disease

Roswell H. Trumpour, Kirtwood, Mo. St. Louis College of Physicians and Surgeons, 1901 member of the Missouri State Medical Association, aged 54, died, Dec. 12, 1930, in Des Peres of pulmonary emphysema

Susan E. Bruce, Lewiston, Idaho, Chicago Homeopathic Medical College 1880 member of the Idaho State Medical Association, formerly member of the state and city boards of health, aged 82, died Dec. 24, 1930

Elisha W. Breazeale, Campit, La., Memphis (Tenn.) Hospital Medical College, 1903 aged 61 died, January 13 in Baton Rouge, of injuries received when the automobile in which he was driving was struck by a train

James A. Miller ☉ McAllen, Texas, American Medical College St. Louis 1901, formerly member of the state board of medical examiners and state legislature in Missouri, aged 69 died Dec. 20, 1930, of pneumonia

George F. Kenney ☉ Milwaukee, Milwaukee Medical College 1906 assistant clinical professor of obstetrics and gynecology Marquette University School of Medicine, aged 46, died January 12, of heart disease

Walter Dancy Minigan ☉ Manchester, N. H., University of Pennsylvania School of Medicine Philadelphia 1920, aged 36 died Dec. 20, 1930, in the Hillsboro County Hospital, Grismere, of cirrhosis of the liver

Walter Fenner Rochelle, Jackson Tenn. Vanderbilt University School of Medicine Nashville, 1882, University of Nashville Medical Department, 1883, aged 73, died, January 9, in Bolivar, of interstitial nephritis

Markley C. Cameron ☉ Pittsburgh University of Pennsylvania School of Medicine, Philadelphia, 1885, aged 69 on the staff of the Western Pennsylvania Hospital, where he died, January 12 of lobar pneumonia

Howard Dysart Kessler, Buffalo, Hahnemann Medical College and Hospital of Philadelphia, 1901 aged 54, died January 10 in the Millard Fillmore Hospital, of coronary occlusion and arteriosclerosis

Abby Dyer Allen, Hamilton, Ohio, Dunham Medical College, Chicago, 1900 Denver College of Physicians and Surgeons 1908 aged 75 died, January 11, in the Fort Hamilton Hospital, of pneumonia

George Washington Lawrence ☉ Litchwood N. J., Yale University School of Medicine New Haven, 1890, on the staff of the Paul Kimball Hospital, aged 61, died, January 16, of cerebral hemorrhage

Stephen A. Foote ☉ Houston Texas, University of Texas School of Medicine, Galveston, 1898, formerly secretary of the Matagorda County Medical Society, aged 60, died, January 7, of coronary thrombosis

Louis H. Davis ☉ St. Louis College of Physicians and Surgeons of St. Louis, 1890, aged 68 died, January 7, in St. John's Hospital of chronic pericarditis with effusion and hypertrophy of the prostate

John M. Jennings, Wamega Kan. State University of Iowa College of Medicine Iowa City, 1872, Civil War veteran, aged 93 died suddenly, January 20, in Warsaw, Ind., of valvular heart disease

Michael Golland, St. Louis Missouri Medical College St. Louis, 1895 member of the Missouri State Medical Association, aged 67 died, January 17, in the Jewish Hospital, of chronic myocarditis

William H. Godwin, Thomas Ala., University of Alabama School of Medicine, Mobile 1909 member of the Medical Association of the State of Alabama, aged 46 died, January 7, of gunshot wounds

George Frederic Wentch Earlville Ill. State University of Iowa College of Homeopathic Medicine Iowa City, 1890,

aged 72, died, Dec 30, 1930, in the East Side Hospital, Waterman, of carcinoma

Edwin Bell Marshall, Annville, Pa (licensed Pennsylvania, 1883), member of the Medical Society of the State of Pennsylvania, aged 76, died, January 6, in a hospital at Lebanon, of uremia

John Moorman Johnson, Rio Hondo, Texas, Louisville (Ky.) Medical College 1894 aged 58, died, Nov 10, 1930 in a hospital at Hurlingen, of cerebral metastasis from an intestinal neoplasm

John Percy Bethel @ Philadelphia, Medico-Chirurgical College of Philadelphia, 1902, served during the World War, formerly city bacteriologist, aged 51, died, January 23, of heart disease

James Winslow Chace, Pittsburgh, University of Buffalo School of Medicine, 1885 formerly member of the school board of Corry, Pa, aged 70, died, Dec. 18, 1930, of cerebral hemorrhage

Edward B Terrell, Atlanta Ga University of Louisville (Ky.) School of Medicine, 1877 aged 73, died, January 12 in the Wesley Memorial Hospital, of heart disease and chronic nephritis

Paul M Donagan, Brookshire Texas, University of Louisville (Ky.) School of Medicine 1889, aged 71, died Dec 27, 1930, in a hospital at Houston, of carcinoma of the urinary bladder

Theodore Clarence Harter, Bloomsburg, Pa, College of Physicians and Surgeons, Baltimore, 1881 formerly member of the state legislature, aged 78, died, in January, of paralysis

Charles Frederick Rinker, Upperville, Va, Bellevue Hospital Medical College, New York 1883, member of the Medical Society of Virginia, aged 71, died Nov 11, 1930 of pneumonia

Harvey Wharton Woods, Blain, Pa, Baltimore University School of Medicine, 1898, Maryland Medical College 1899, aged 59, died, Dec 13 1930, of carcinoma of the throat

Jefferson T Hartly, Liverpool W Va Miami Medical College, Cincinnati, 1882, aged 78, died, Nov 11, 1930, in Clifton Forge, of heart disease and chronic nephritis

John K Ross, Mishawaka, Ind Eclectic Medical Institute, Cincinnati 1881, aged 85, died, January 12, of acute arthritis of the left elbow, following infection of the thumb

Solomon R McKay, Troy, Mo St Louis Medical College 1875, aged 76, died January 5 in St Anthony's Hospital, St Louis, of arteriosclerosis and diabetes mellitus

John Mitchell Gibson @ McIndoe Falls, Vt University of Vermont College of Medicine, Burlington 1888, aged 68, died, Dec 29, 1930, in Berea, Ky, of nephritis

James A Ward, Cordele, Ga, Atlanta Medical College, 1891, member of the Medical Association of Georgia, aged 62, died January 10, of cerebral hemorrhage

William Jackson Smith, Desoto, Ga Kentucky School of Medicine, Louisville 1890, member of the Medical Association of Georgia, aged 65, died, Nov 8 1930

Jose Gomez Brioso @ San Juan P R Central University of Spain Faculty of Medicine, Madrid, 1879 aged 76, died, Oct 17, 1930, of bronchopneumonia

Marcus Henry Heldman, Pasadena Calif University of Nashville Medical Department, 1906, aged 58, died, January 16, of a self-inflicted bullet wound

Alexander Rae, Brooklyn Long Island College Hospital, Brooklyn, 1885, member of the American College of Surgeons aged 70, died, January 5

Hugh Payne Hirst, Leetown W Va Baltimore Medical College, 1895 aged 71 died Dec 20 1930 in Shepherdstown, of cerebral hemorrhage

John B Haines Lima Ohio Fort Wayne (Ind) College of Medicine 1879 aged 78, died January 3 of senile dementia and arteriosclerosis

Tilman Johnson Robb @ North Fork Ky University of Louisville School of Medicine 1908 aged 49 died, January 9, of pneumonia

Henry Lewis Gunn Halifax, Va Medical College of Virginia Richmond, 1899 aged 60, died January 4 of pneumonia

Bernard W Shirey @ York Pa College of Physicians and Surgeons, Baltimore 1895 aged 58 died Dec 5 1930 of peritonitis

Charles J Cragg Detroit Detroit College of Medicine 1900 aged 63 died Dec 3 1930, of carcinoma of the throat

Bureau of Investigation

BRINKLEY'S BROADCASTING STATION

Appellate Court Sustains the Radio Commission

Some time ago, the Federal Radio Commission refused to renew the broadcasting license of Station KFKB of Milford, Kansas, operated by John R Brinkley. The Commission's refusal to renew was based on the ground that the station was operated mainly in the interests of Brinkley rather than in the interests of the public. Following this decision on the part of the Federal Radio Commission Brinkley appealed the case to the courts. On February 2, 1931, the Court of Appeals of the District of Columbia affirmed the Federal Radio Commission's position. The full text of the Appellate Court's decision follows:

In the Court of Appeals of the District of Columbia

KFKB BROADCASTING ASSOCIATION, INC. *Appellant* } No 5240
FEDERAL RADIO COMMISSION }
(Before Martin Chief Justice and Robb and Van Orsdel Associate Justices)

Appeal from a decision of the Federal Radio Commission denying appellant's application for the renewal of its station license

The station is located at Milford, Kansas is operating on a frequency of 1050 kilocycles with 5000 watts power, and is known by the call letters KFKB. The station was first licensed by the Secretary of Commerce on September 20 1923 in the name of the Brinkley-Jones Hospital Association, and intermittently operated until June 3, 1925. On October 23, 1926 it was relicensed to Dr J R Brinkley with the same call letters and continued to be so licensed until November 26 1929, when an assignment was made to appellant corporation.

On March 20 1930 appellant filed its application for renewal of license (*Radio Act of 1927, c 169, 44 Stat 1162 U S C Supp III, Tit 47, Sec 81, et seq*). The Commission finding to find that public interest, convenience or necessity would be served thereby accorded appellant opportunity to be heard. Hearings were had on May 21, 22, and 23, 1930 at which appellant appeared by counsel and introduced evidence on the question whether the granting of the application would be in the public interest, convenience or necessity. Evidence also was introduced in behalf of the Commission. Upon consideration of the evidence and arguments, the Commission found that public interest, convenience, or necessity would not be served by granting the application and, therefore, ordered that it be denied effective June 13, 1930. A stay order was allowed by this Court and appellant has since been operating thereunder.

The evidence tends to show that Dr J R Brinkley established station KFKB, the Brinkley Hospital and the Brinkley Pharmaceutical Association and that these institutions are operated in a common interest. While the record shows that only three of the 1000 shares of the capital stock of appellant are in Dr Brinkley's name and that his wife owns 381 shares it is quite apparent that the Doctor actually dictates and controls the policy of the station. The Brinkley Hospital located at Milford, is advertised over Station KFKB. For this advertising the hospital pays the Station from \$5,000 to \$7,000 per month.

The Brinkley Pharmaceutical Association formed by Dr Brinkley, is composed of druggists who dispense to the public medical preparations prepared according to formulas of Dr Brinkley and known to the public only by numerical designations. Members of the Association pay a fee upon each sale of certain of these preparations. The amount thus received is paid the Station presumably for advertising the preparations. It appears that the income of the Station for the period February, March, and April 1930, was as follows:

Brinkley Pharmaceutical Association	\$5,000.00
Brinkley Hospital	1,000.00
All other source	400.00
Total	\$6,400.00

Dr Brinkley personally broadcasts during three regular periods daily over the station the broadcast being returned to

the "Medical Question Box" and is devoted to diagnosing and prescribing treatment of cases from symptoms given in letters addressed either to Dr Brinkley or to the Station. Patients are not known to the Doctor except by means of their letters, each letter containing a code signature which is used in making answer through the broadcasting station. The Doctor usually advises that the writer of the letter is suffering from a certain ailment and recommends the procurement from one of the members of the Brinkley Pharmaceutical Association, of one or more of Dr Brinkley's prescriptions, designated by numbers. In Dr Brinkley's broadcast for April 1, 1930, presumably representative of all, he prescribed for forty four different patients and in all save ten, he advised the procurement of from one to four of his own prescriptions. We reproduce two as typical.

Here's one from Tillie. She says she had an operation had some trouble 10 years ago. I think the operation was unnecessary and it isn't very good sense to have an ovary removed with the expectation of motherhood resulting therefrom. My advice to you is to use Women's Lonic No 50, 67 and 61. This combination will do for you what you desire if any combination will, after three months persistent use.

Sumflower State from Dr. John Jones. Probably he has gall tone. No I don't mean that I mean kidney stones. My advice to you is to put him on Prescription No 80 and 50 for men and 10. I think that he will be a whole lot better. Also drink a lot of water.

In its "Facts and Grounds for Decision" the Commission held "that the practice of a physician prescribing treatment for a patient whom he has never seen and bases his diagnosis upon what symptoms may be recited by the patient in a letter addressed to him is inimical to the public health and safety, and for that reason is not in the public interest", that "the testimony in this case shows conclusively that the operation of Station KFKB is conducted only in the personal interest of Dr. John R. Brinkley. While it is to be expected that a licensee of a radio broadcasting station will receive some remuneration for serving the public with radio programs, at the same time the interest of the listening public is paramount, and may not be subordinated to the interests of the station licensee."

This being an application for the renewal of a license, the burden is upon the applicant to establish that such renewal would be in the public interest, convenience, or necessity (*Technical Radio Lab v Fed Radio Comm — App D C —, 36 F (2d) 111, 114 Campbell v Galeno Chem Co 281 U S 599 609*) and the court will sustain the findings of fact of the Commission unless manifestly against the evidence" (*Ansley v Fed Radio Comm, No 5149, decided this term, — App D C —, — F (2d) 111*).

We have held that the business of broadcasting, being a species of interstate commerce, is subject to the reasonable regulation of Congress (*Technical Radio Lab v Fed Radio Comm, — App D C — 36 F (2d) 111, City of New York v Fed Radio Comm, — App D C —, 36 F (2d) 115, Chicago Federation of Labor v Fed Radio Comm, — App D C —, 41 F (2d) 422*). It is apparent, we think, that the business is impressed with a public interest and that, because the number of available broadcasting frequencies is limited, the Commission is necessarily called upon to consider the character and quality of the service to be rendered. In considering an application for a renewal of the license, an important consideration is the past conduct of the applicant, for "by their fruits ye shall know them" (*Matt 12:12*). Especially is this true in a case like the present, where the evidence clearly justifies the conclusion that the future conduct of the station will not differ from the past.

In its Second Annual Report (1928), p. 169, the Commission cautioned broadcasters "who consume much of the valuable time allotted to them under their licenses in matters of a distinctly private nature which are not only uninteresting, but also distasteful to the listening public." When Congress provided that the question whether a license should be issued or renewed should be dependent upon a finding of public interest, convenience, or necessity it very evidently had in mind that broadcasting should not be a mere adjunct of a particular business but should be of a public character. Obviously, there is no room in the broadcast band for every business or school of thought.

In the present case while the evidence shows that much of appellant's programs is entertaining and unobjectionable in character, the finding of the Commission that the station "is conducted only in the personal interest of Dr. John R. Brinkley

is not "manifestly against the evidence." We are further of the view that there is substantial evidence in support of the finding of the Commission that the "medical question box" as conducted by Dr Brinkley "is inimical to the public health and safety, and for that reason is not in the public interest."

Appellant contends that the attitude of the Commission amounts to a censorship of the station contrary to the provisions of Sec 29 of the Radio Act of 1927. This contention is without merit. There has been no attempt on the part of the Commission to subject any part of appellant's broadcasting matter to scrutiny prior to its release. In considering the question whether the public interest, convenience, or necessity will be served by a renewal of appellant's license, the Commission has merely exercised its undoubted right to take note of appellant's past conduct, which is not censorship.

As already indicated Congress has imposed upon the Commission the administrative function of determining whether or not a station license should be renewed, and the Commission in the present case has in the exercise of judgment and discretion ruled against the applicant. We are asked upon the record and evidence before the Commission to substitute our judgment and discretion for that of the Commission. While Sec 16 of the Radio Act of 1927 (*44 Stat 1162 1169, U S C, Supp III, 1st 47 sec 96*) authorized in appeal to this Court, we do not think it was the intent of Congress we should disturb the action of the Commission in a case like the present. Support is found for this view in the Act of July 1, 1930 (*46 Stat 844*), amending Sec 16 of the 1927 Act. The amendment specifically provides that the review by the court shall be limited to questions of law and that findings of fact by the commission, if supported by substantial evidence, shall be conclusive unless it shall clearly appear that the findings of the commission are arbitrary or capricious. As to the interpretation that should be placed upon such provision see *Ma-King v Blair*, 271 U S 479, 483.

We are therefore constrained, upon a careful review of the record to affirm, the decision.

Affirmed

NATIONAL ADJUSTING ASSOCIATION

To the Editor —In the fall of 1928, a representative of the National Adjusting Association, 208 West Washington Street, Chicago, called on me, and by the most unscrupulous canvass ever inflicted on me induced me to give him a list of slow accounts amounting to \$6,000. I was to have monthly reports and checks with each. To my surprise, they got money from most unexpected sources—but the last check I received was May 9, 1929. I have persistently demanded an accounting from time to time, since, without effect. They dodge the issue by some demand or proposal which is necessary before they can act, and so they dangle along, evading a report.

I have written the Department of Law Enforcement in Boise to see if these people are legally qualified since 1928 to operate in this state, and I believe it would be well to give this matter a little publicity through THE JOURNAL. I am convinced the medical profession would much rather allow their earnings to remain in the hands of their clientele—even though that clientele neglects its duty—than to turn it into less worthy channels.

C F MAGEE, M D, Moscow, Idaho

[COMMENT—The National Adjusting Association was one of the organizations that was given some publicity in the Bureau of Investigation department of THE JOURNAL, June 10 1922. Since that time we have had many additional complaints regarding the concerns methods, some of which have been only partially justified, while others seem to have been well justified. The company so far as we know, keeps within the terms of

its contract, but the contract itself is an inequitable one that seems to be made almost wholly in the interests of the collection agency, rather than equally in the interests of the agency and its client. While Dr. Magee understood that he was to have monthly reports and remittances from the collection agency, the National Adjusting Association's contracts that we have seen says nothing about such monthly reports. It does say that the physician must immediately report to the collection agency and send its share of payments made directly to the physician. But there is nothing in the contract requiring the agency itself to write to the doctor until it gets ready.—ED.]

ROBISON NATIONAL CLEARING AND WORLD WIDE ADJUSTING COMPANIES

To the Editor—I was interested in your article on the Robison National Clearing Company of Albany, N. Y. I have had a little experience with this company and believe that you should know about these things. In February, 1930, a representative of the World Wide Adjusting Company (a subsidiary of the Robison National Clearing Company) called at my office and asked that I give him some of my bad accounts, stating that his company was going to compile a book of Lagrange County, listing all "dead beats" whom they owed, etc. He stated that every one who turned over any accounts to him would secure one of these books. He canvassed business houses in town telling the same story. He had a booklet, which he showed me on another county, similar, he said, to the one to be prepared on Lagrange County.

Being new and unacquainted in this community, I gave him a few bad accounts, because I felt that this proposed booklet might be of some use to me. Two of the claims I turned over were not to be pressed until further word from me. A few weeks later I received a notice from this company, stating they were pressing my claims, including these two. I wrote telling of the understanding with their representative and received their reply of April 4. On August 1, I wrote asking about the listing book and received their reply of August 7.

I have no particular grievance with them. They have done me neither good nor harm, but I thought you might be interested in knowing these things. You will note that while the address is the same, the name is different from the company on which you published. FRANK J. KENDRICK, M.D., Lagrange, Ind.

[EDITORIAL COMMENT—Dr. Kendrick enclosed with his communication some letters received from the World Wide Adjusting Company (which also seems to go under the name of World Wide Adjusting Association, Inc.) With reference to the two claims that the doctor had stated should not be pushed the company agreed to discontinue further action on them. As to the complaint of Dr. Kendrick, that the listing book had not been received. The company wrote that it published no such book, that it was in the collection business only and expressed the opinion that its representative might be "carrying such a proposition as a side line." A later letter from the company, following the doctor's further protest, brought the statement that they were checking up the matter with their representative and in the meantime, would withhold further service on the doctor's claims. The company also stated in this letter that it was a subsidiary of the Robison National Clearing Company of the same address. Finally, in a letter dated December 16 the World Wide Adjusting Company wrote in effect that the investigation had shown that their agent had made representations that were unjustified and for that reason the company was closing its files and making no further attempt to collect the doctor's accounts. The information was added that the company's representative in this case was one R. E. House and not the man Rosenkrans whose methods were discussed in THE JOURNAL's article on the Robison National Clearing Company.]

To the Editor—I have had an experience with the Robison National Clearing Company of Albany, N. Y. very similar to that of Dr. L. O. Price of Ladoga, Ind. Last March a Mr. P. T. Rosenkrans representing the above named company called

on me and represented that they were getting up a credit book and wanted a list of my delinquent accounts, offering to collect them for 50 per cent of the first \$100 collected and 15 per cent of all after the first hundred. He said that I did not have to sign any contract and that I would receive a credit book in due time with a rating of people in Tippecanoe and adjoining counties. I did not sign any contract. In a few days I received two lists from the company at Albany, asking me to look them over, correct any errors, sign one and return the other.

I sent them a telegram telling them the list was not correct and not to proceed with any collections. It seems that they sent their first notice to my accounts at the same time they mailed me the lists. A few people came to my office and paid me and I sent the commission agreed with Mr. Rosenkrans, telling them I was sending the commission because they had apparently sent the notice before they received my telegram.

They have failed to send me any money they have collected. Have been very offensive to my patients, threatening suits and attachments on their furniture, autos, etc. I have repeatedly ordered them to stop but they have refused, saying I had signed a contract assigning the accounts to them. They finally sent to Battle Ground State Bank what they said was a contract signed by me. This was a rank forgery, as the president and other officers of the bank are willing to testify to. They still refuse to send me any money they have collected. They are still threatening some of my patients with suits.

FRANK M. BIDDLE, M.D., Battle Ground, Ind.

To the Editor—I have read with interest the article on the experience of an Indiana physician with the Robison National Clearing Company, Inc. appearing in the Bureau of Investigation Department of THE JOURNAL, December 13. About four or five years ago, in a weak moment, I contracted with them to collect around a thousand odd dollars' worth of accounts. To date, in spite of repeated attempts, I have been unable to collect one single cent from them, although, on their own admission, they have made several collections. I have had a somewhat similar experience with the United States National Adjustment Company of Chicago.

H. F. W. WARREN, M.D., Detroit

ADENOCARCINOMA OF THE HEAD OF THE PANCREAS

To the Editor—I have read with great interest the article by Dr. Elmer Hess on this subject in THE JOURNAL, January 3. Dr. Hess is to be commended for calling attention to the difficulties of diagnosis of lesions in the region of the head of the pancreas.

I wish to call attention to several diagnostic aids which have been found useful in a consideration of these lesions. The duodenum has approximately the same shape as that of a horse shoe magnet, the pyloric end of the stomach forming the bar between the poles of the magnet. A tumor mass within the loop tends to expand the latter, often to such an extent that the horse shoe becomes a circle. Clarence Bird has emphasized the value of repeated series of roentgenograms over a period of time. Any expansion is suggestive of a growing tumor mass within the duodenal loop. This expansion can be conveniently detected by a suitable technique measuring vertical and horizontal measurements on the roentgenogram. Contour tracings can also be made and compared.

Carcinoma of the pancreas may invade the duodenum. In the early stages of the process the filling defects so produced are evanescent and difficult to detect. Roentgenograms therefore are quite essential to supplement the radioscopic observation.

JOHN R. CARTY, M.D., New York

Chief of Clinic, Department of X-ray
Cornell University Medical College

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address but these will be omitted on request.

INDICATIONS FOR AND TECHNIC OF CISTERNAL PUNCTURE

To the Editor—Please describe the technic of doing a cisternal puncture in order to obtain a specimen of cerebrospinal fluid. Is there any danger of performing routine cisternal punctures instead of lumbar spinal punctures? Please omit name and address. M D North Dakota

ANSWER—The technic of doing a cisternal puncture is adequately described in Ayer's article in the *Archives of Neurology and Psychiatry* 4:529 (Nov.) 1920. In brief, the hair of the back of the neck is shaved to the external occipital protuberance. The area in the midline from this point to the second cervical spine is painted with iodine. The patient is in a position so that his head is on a straight line with his cervical spine. The neck is flexed anteriorly about 20 degrees. The thumb of the left hand palpates and finds the midline in the area between the external occipital protuberance and the spine of the second vertebra. The needle is inserted inward at an angle so that it points in a line between the external auditory meatus and the glabella. The needle should never be inserted more than 6 cm. It passes through the subcutaneous tissue and the musculature, and strikes the firm resistant occipito-atlantoid ligament. It takes considerable pressure to pass through this portion of the dura and care must be exerted that the needle is not pushed too far anteriorly by the force that is required to penetrate the dura. Difficulties in obtaining fluid are usually due to being outside the midline or not directing the needle in the proper direction. Anomalous veins sometimes give rise to bleeding and when this occurs no further puncture should be done in the cisternal region. Routine cisternal puncture should not be done instead of lumbar punctures as there is some danger to the former and certain deaths have been described actually due to the puncture, whereas lumbar spinal punctures are entirely free from danger when contraindications to withdrawal of fluid do not exist.

TREATMENT OF SYPHILIS—ADVICE TO SYPHILITIC PATIENT CONCERNING MARRIAGE—LAWS REGULATING MARRIAGE

To the Editor—I have a patient whose diagnosis was primary syphilis (chancre) diagnosed by clinical observations and by the dark field. He received six intravenous injections of neovarsphenamine and nine intramuscular injections of bismuth. If his Wassermann reaction should be negative would you repeat the same course of treatment for two years? The Army Manual directs the giving of mercurial treatment only if the first Wassermann reaction is negative and a return to the intravenous treatment if the Wassermann reaction is positive. 1. Do many other authorities agree with directions given in this manual on venereal diseases? 2. How long would you have the patient wait after the primary lesions have healed up to get married? 3. What states in the Union require a medical examination before obtaining a marriage license? What states require this examination only from the man and what states require the same examination of both sexes?

WILLIAM FRANKMAN M.D. Boston

ANSWER—1 and 2. The directions given by the Army Manual are derived from teachings of prominent syphilologists and may therefore be considered authoritative. It is the consensus that an individual has to be free from all syphilitic symptoms for at least one year before marriage should be contemplated. The patient must not only be free from all symptoms to be discovered by clinical examinations but also be tested by serologic examinations which includes the testing of the spinal fluid.

3. No American state requires a prospective bride to furnish a medical certificate showing that she has been examined and found free from venereal disease. Seven states require such examinations and certificates from prospective bridegrooms, namely Alabama, Louisiana, North Carolina, North Dakota, Oregon, Wisconsin and Wyoming.

The marriage of a person who has a contagious venereal disease is forbidden in Delaware, Indiana, Maine, Michigan, Nebraska, New Jersey, Oklahoma, Pennsylvania, Utah, Vermont, Virginia and Washington. We are not informed however as to the method of enforcing compliance with the several statutes of the states named except that the laws of Pennsylvania

require an application for a marriage license to contain a statement showing that neither party has a transmissible disease.

In New Jersey, it is unlawful for any person who has been confined in any public asylum or institution as an epileptic, insane or feeble-minded person to intermarry without a certificate from two regularly licensed physicians of New Jersey, that such person has been completely cured of such insanity, epilepsy or feeble-mindedness and that there is no probability that such person will transmit any such defect or disability to the issue of such marriage.

The marriage of epileptic persons is forbidden in Delaware, Indiana, Kansas, Minnesota, Missouri, North Dakota, Ohio, Utah, Virginia and Washington. We are not informed as to the method of insuring compliance with these statutes.

The laws of Pennsylvania require that an application for a marriage license contain a statement showing that neither party has a transmissible disease. This seems to be broad enough to cover venereal diseases in their communicable stages, hemophilia, and transmissible disorders of the nervous system.

OBSTETRIC DEATHS IN AND OUT OF HOSPITAL

To the Editor—In a recent discussion with physicians from rural communities there was a difference of opinion as to the percentage of deaths in obstetric cases in and outside of hospitals. For my own information and to settle the argument I should like figures concerning the death rate in these cases both in hospitals and out of hospitals. Also an opinion as to why the difference in death rate in such cases.

REV. LEWIS D. HOPPER, Peoria, Ill.

ANSWER—There is little direct evidence in the literature bearing on the question of the percentage of deaths in obstetric cases in and outside of hospitals. There are no figures that pertain to the country as a whole. This question was taken under consideration by a subcommittee of Section I of the White House Conference on Child Health and Protection which recently met in Washington, D. C., and the report of the subcommittee stated that: "There is not much available material on this subject as bureaus of vital statistics do not usually classify maternal deaths according to the place of delivery. Figures secured from California for 1929, however, show that the rate was practically the same for hospital and home deliveries. This is a very good showing for the hospitals in view of the fact that they receive a large proportion of complicated and difficult cases."

An article published in *THE JOURNAL* Nov. 9, 1929, by Holmes, Munsey and Adair included a study of maternal deaths made by the Minneapolis Infant Welfare Society following home and hospital deliveries during the years 1925 to 1928 inclusive. There was a total of 35,583 living births during the period studied of which 24.2 per cent took place in homes and among these the death rate per thousand was 3.4. Of the total number of living births, 75.8 per cent took place in hospitals and among these the maternal death rate per thousand was 3.9.

Frankel in a pamphlet published in 1927 by the Metropolitan Life Insurance Company on *The Present Status of Maternal and Infant Hygiene in the United States*, said that some five years ago Dr. Julius Levy made a study of maternal mortality among cases attended in the homes by midwives and compared them with all the cases attended in Newark, N. J., during the period 1916 to 1921. On cases ever handled by a midwife, there occurred 15 maternal deaths per thousand births and for the whole city, including the midwife cases, the rate was 4.3 per thousand births. Frankel said it is interesting to inquire whether this favorable record was due to attendance of midwives or to the fact that the deliveries took place in the home, and presumably without undue meddling or tampering.

BREEDING OF MOSQUITOES

To the Editor—1. Do not the majority of mosquitoes that infest the seacoast breed in salt water or brackish water caused by the tides and swamps? 2. Is it possible that the anopheles may breed in brackish water? 3. What species of mosquitoes breed in salt water and in brackish water? Kindly omit my name. M D South Carolina

ANSWER—1. The percentage of species of mosquitoes that breed in brackish water along the seacoast varies greatly in different parts of the world. In many places, however, a large proportion of the mosquitoes along the coast breed in brackish water. An example of this is found in the salt marsh mosquitoes of New Jersey.

2. A number of anophelines breed in brackish and a few in sea water. In the United States according to Griffiths,

Anopheles crucians will breed in 50 per cent sea water and *A. quadrimaculatus* in 15 per cent sea water. In parts of Porto Rico tidal swamps are of great importance in the breeding of *A. albimanus* and in the control of malaria.

3 It is impossible to list all of the known salt-water breeders. In the United States, besides the anophelines listed in 2, the best known are *Aedes sollicitans*, *A. taeniorhynchus* and *A. cantator*. The whole question of the effect of salinity on mosquito breeding is attracting considerable attention and future work will probably uncover a number of instances in which species thought to breed only in fresh water will be found to breed also in brackish water.

STAPHYLOCOCCI IN BLOOD CULTURES

To the Editor—What are the clinical conditions that would tend to be confirmed by the isolation of staphylococci in hemoculture? If staphylococci are found on hemoculture is a person justified in regarding them as contaminants due to faulty technique unless there is some clinically recognizable localized septic process? Please omit name.

MD Idaho

ANSWER—The mere demonstration of the presence of staphylococci in a blood culture without determination of the virulence of such organisms is of little value. There is no sure way of differentiating staphylococci that may be contaminations from the skin from those that invade the blood stream in septic infections, other than the virulence test in suitable animals. Intravenous injection into rabbits is perhaps the best method of determining virulence or specific invasive power of staphylococci which may appear in blood cultures.

TREATMENT OF CONGENITAL SYPHILIS

To the Editor—A girl aged 6 years with congenital syphilis first came to me for treatment at the age of 5. She had had in early infancy a brief course of antisyphilitic therapy at which time she had a chronic suppurative cervical lymphadenitis. The physician who treated the lymphadenitis stated that the cervical glands were probably syphilitic as they had discharged for a long time and healed only after antisyphilitic therapy had been instituted. I do not know how much treatment she had in infancy but she had had no treatment for several years previous to coming to me. Physical examination was negative except for malnutrition (weight 35 pounds or 16 Kg.) hypertrophied infected tonsils and adenoids but no other stigmas of syphilis. The child seemed normal mentally and a neurologic examination was negative. The blood Wassermann reaction was 4 plus and has remained so since. I have given the following treatment over a period of fifteen months:

8-1-29—9-31-29	Sulpharsphenamine in transmuscularly 5 injections 12 Gm	1 per cent mercuric chloride intramuscularly 5 injections 0.5 cc
10-8-29—1-4-30	Sulpharsphenamine 4 injections 0.2 Gm	Mercuric salicylate 12 injections 3-100 1/10 grain
2-15-30—5-10-30	6 injections 0.2 Gm	12 injections 4-100 grain
7-12-30—8-9-30	5 injections 0.2 Gm	5 injections 4-100 grain
9-13-30—11-15-30	10 injections 0.2 Gm	10 injections 4-100 grain

The total treatment over a period of fifteen months was sulpharsphenamine thirty injections 0.2 Gm each 1 per cent mercuric chloride five injections 0.5 cc each mercuric salicylate thirty nine injections 3-100 1/10 grain each. The child has remained well except for minor cold and chickenpox and seems normal except for failure to gain (her weight now is only 36 pounds or 16.3 Kg.) which I ascribe as much to the infected tonsils and adenoids as to the syphilis. Is the treatment I have described adequate or inadequate? In another month I plan to start the patient on a course of ten weekly injections of sulpharsphenamine 0.3 Gm each followed immediately by ten weekly injections of bismuth subsalicylate, 0.4 Gm each then a vacation of one or two months followed by a repetition of this course and so on. Does such a program alternating mercury sulpharsphenamine and bismuth appear to you to be adequate? What do you think of the use of potassium iodide? I feel that it is indicated but do not know when how often or how much to use. It seems to me that the chances of getting the patient Wassermann negative after so long a period of neglect are not especially good. If after another year of treatment the Wassermann reaction is still positive how should I proceed? If the Wassermann remains positive but the child remains well how am I to judge as to the adequacy of my treatment? In such a case must treatment be continued indefinitely at (a) short intervals or (b) at long intervals? Please omit name.

MD Ohio

ANSWER—The main facts in this child's case are these: The first evidence of her syphilitic infection took the form of a Vignolo-Luttray syndrome which always raises the question of intercurrent tuberculosis as well as gummatous syphilis. She shows definite evidence that she is carrying the handicap of a chronic intercurrent infection in the form of the hypertrophied

infected tonsils and adenoids. She has a strongly positive blood Wassermann reaction that has resisted quite energetic treatment. She is still within the interstitial keratitis period in the life history of a prenatal syphilitic infection, and the possibility of this complication whether with or without treatment, must be constantly kept in mind. While she is normal to neurologic examination asymptomatic neurosyphilis can occur and not infrequently does in prenatally infected children, and for that reason a spinal fluid examination is a necessary part of any investigation for the explanation of the persistent positive blood Wassermann reaction. It is suggested, therefore, that since the amount of treatment already received is probably sufficient to protect against any gummatous accident the handicap of the infected hypertrophied tonsils and adenoids be removed at the earliest possible date. This will in all probability favorably influence the child's nutrition and general state of health. It seems essential, also, to have a spinal fluid examination at some time in the not too distant future and this might conceivably be done during the general anesthesia employed for the removal of the tonsils, though the possibility of stirring up a focal infection and transferring what might be a shower of organisms in the blood stream to the meninges makes it, perhaps rather more desirable to do the lumbar puncture as an entirely separate procedure.

With regard to the continuance of treatment, there is probably no further need for mercury for it has been quite clearly shown that bismuth compounds and an arspenamine are all that is needed for the effective management of latent prenatal syphilis. It seems possible that the blood Wassermann reaction will not reverse in this case under any form of treatment and such reversal should not be made so much of an object that the child is kept under too prolonged or too intensive a regimen. Another year of alternating sulpharsphenamine and bismuth would justify a rest period of several years while the child is kept under observation all this provided the spinal fluid examination is completely negative to all four of the conventional tests. The adequacy of treatment in such a case must be gauged by general constitutional response even more than by serologic reaction. It must be remembered too that it has not yet been clearly shown that even the most energetic modern treatment is able absolutely to insure against the onset, in the coming years of this child's life, of a severe attack of interstitial keratitis. It is essential, therefore, to hold a certain amount of treatment tolerance in reserve to deal with such a situation in case it arises. There are, of course, objections to the use of sulpharsphenamine particularly the tendency markedly greater than that of other arspenamines to induce exfoliative dermatitis. Bismuth arspenamine sulphurate or bismuth alone will give quite satisfactory results with less risk on this score. Potassium iodide is always indicated in prenatal syphilitic infection the dose being moderate from 0.65 to 1.3 Gm (10 to 20 grains) three times a day, given preferably during rest periods from other treatment.

MILD MERCUROUS CHLORIDE SUSPENDED IN LIQUID

To the Editor—After examining patient and making a diagnosis I prescribed

	Gm or Cc
R Tincture of belladonna	1
Calomel (O.K. to fill)	2
Sodium bicarbonate	12
Aromatic fluidglycerate of cherry sagrada	12
sufficient to make 120	

M Sig. Ten spoonful every three hours in water

In an hour I received a phone call from the local druggist in reference to the dose of calomel. I advised him that the dose was what I wrote and thought was indicated in this case—in fact, even labeled for crying in so that effect in order to relieve him of any responsibility. However, he insisted that 1 grain was an overdose for every three hours (practically 5 grains per diem) and would not fill it. So I advised him to return the prescription to the patient that he might have it filled somewhere else. It was filled by another pharmacist without question. The patient was continued for two days. The patient is entirely well and content. I would like to know what is wrong with a dose of 1 grain of calomel when U.S.P. Cathartic pills contain 1 grain and can be bought anywhere and used at random.

M. K. M.D. Chicago

ANSWER—Prescribing such a heavy in soluble substance as mild mercurous chloride in liquid dosage form is unadvisable because of necessary inequality of dosage. Even if the mixture is shaken each time before taking the mild mercurous chloride will settle so rapidly that the last doses will contain much more of it than the first. Nevertheless even if the 2 Gm contained in the mixture were taken at one time the patient having refrained from shaking the bottle no dire result could have followed unless an intestinal obstruction was present. In such a case mercurial poisoning might have resulted. The pharmacist was within his legal right in refusing to fill a prescription that

he considered potentially dangerous, for, in spite of the physician's insistence that the dosage was intended, the pharmacist would have been held legally responsible with the physician in case harm resulted from the medicine. The pharmacist who filled the prescription took a risk, even though a slight one.

TREATMENT OF ECZEMA OF EXTERNAL EAR

To the Editor—Kindly inform me regarding the treatment of chronic eczema of the external ear canal. The patient's present ailment is of one and one-half years duration, and it is very annoying because of severe itching, and pruritus at times. Would quartz light treatments benefit this condition? His tonsils seem to be infected. Would tonsillectomy be necessary besides the usual local treatments? Please omit name and address.

M D New Jersey

ANSWER—Before making local applications to the ear canal, it should be cleansed with a swab dipped in oil or liquid petrolatum. Then, once or twice a day, the following should be applied:

	Gm	or	Cc
Rectified oil of birch tar N F	1.0		gr xxx
Resorcinol	0.8		gr xiii
Liquid petrolatum	to make	16.0	ss

This should relieve the itching and gradually clear up the chronic inflammation.

Ultraviolet radiation is difficult to apply in the ear canal. X-rays, one-half skin unit filtered through 1 mm of aluminum, can be given once a week and are often successful in relieving the itching and causing resolution of the condition. They should be given through an opening in a sheet lead mask, so that only the skin immediately around the opening of the canal is exposed, and should not be continued after relief is obtained, nor after eight treatments as outlined have been given.

The tonsils would have only an indirect influence on this eczema, through their effect on the general health.

USE OF METHENAMINE AND SODIUM ACID PHOSPHATE

To the Editor—Many of the drug concerns market a tablet consisting of methenamine and sodium acid phosphate in varying amounts. They state that the drug should be taken in water. Useful Drugs states that the two should not be prescribed in solution. The coming of methenamine and sodium acid phosphate in tablet form makes the medication easier for the patient but because of the foregoing statement I should like to know whether this combination taken in solution is proper. Please omit name and address.

M D New York

ANSWER—There is really no serious incompatibility if methenamine and sodium acid phosphate are prescribed in a relatively fresh solution. Prescribing them separately in tablet form is, on the whole, still better. According to Useful Drugs, the acid phosphate should preferably be given long enough in advance of the methenamine so that it will have left the stomach before the latter is administered. Sodium acid phosphate should be administered preferably as a separate prescription, until the urine is acid. If the urine is unacidified, there is no need of constant dosing with sodium acid phosphate while the methenamine is being taken.

OSTELIN—PROGNOSIS IN PAGET'S DISEASE

To the Editor—What is the prognosis and treatment for Paget's disease of the bones? Is the ultraviolet ray of use? In London they use a remedy called Ostelin which they think of value. Can you tell me where it can be obtained? Please omit name and address.

M D Maine

ANSWER—Ostelin is marketed in Great Britain as a cod liver oil concentrate. A reference to Ostelin appears in the *Lancet*, Sept 3, 1927, page 508. No examination of Ostelin has been made by the Council on Pharmacy and Chemistry. The following cod liver oil concentrates have been accepted by the Council: Ocodol White's Cod Liver Oil Concentrate, and McKesson's Vitamin Concentrate of Cod Liver Oil.

The prognosis in Paget's disease is very poor. The treatment for Paget's disease is unknown. Ultraviolet rays may be of benefit in reducing the rheumatic symptoms and maintaining tonicity of the muscles.

DANGERS OF GUAIASODIDE INTRAVENOUSLY

To the Editor—Two weeks ago for five days I gave a patient who had bronchial asthma one 20 cc ampule daily of Guaiasodide (Breon) which contains sodium iodide 32 Gm, guaiacol 0.625 Gm, creosote 0.625 Gm, and dextrose 5 Gm. A week ago the patient developed a phlebitis in both arms which has continued to become worse. Was the solution irritating to the veins and did this account for the phlebitis?

JAMES ANDREW M D Cordova Ala

ANSWER—Evidently

Medical Education, Registration and Hospital Service

New Hampshire September Examination

Dr Charles Duncanson, secretary of the State Medical Board New Hampshire, reports the oral, written and practical examination held at Concord, Sept 11-12, 1930. The examination covered 9 subjects and included 90 questions. An average 75 per cent was required to pass. One candidate was examined and passed. The following college was represented:

College	PASSED	Year Grad	Reciprocity
Harvard University Medical School		(1925)	81

Dr Duncanson also reports 12 physicians licensed through reciprocity with other states and 2 by the endorsement of credentials at the same meeting. The following colleges were represented:

College	LICENSED BY RECIPROCITY	Year Grad	Reciprocity
State University of Iowa College of Medicine		(1923)	16

Book Notices

APHASIA IN CHILDREN. By Alex W G Ewing M A Ph D With an introduction by E D Adrian M D FRCP FRS Cloth Price 3 50 Pp 152 New York Oxford University Press 1930

Ewing states that in the speech and language development of the normal child the essential processes are first hearing and then learning to understand and to imitate the spoken word. In the absence of hearing, neither understanding of words, speech, reading nor writing develop naturally. The author emphasizes the importance of testing the hearing of all children suspected of aphasia. He reviews in detail the various hearing tests, including the Rinne (tuning fork test of air and bone conduction), watch test, whispered speech, phonograph audiometer, tonoscope and sensitive flame and the audiometer. The last mentioned instrument is a model 2 A Western Electric Company audiometer and is used in the course of the author's investigations. The audiometer as a means of testing hearing is found to give quantitative measurements of a range and accuracy unobtainable with any other known form of apparatus and it has made known the existence of hearing in children who had been considered totally deaf to sound. The author discovered that among individuals whose hearing is apparently normal, differences in auditory acuity may occur all over the tonal range. Furthermore, the sense of hearing is not the same in any two individuals. He made the important discovery that a hearing defect occurred which he termed high-frequency deafness. Five boys and one girl were found to suffer from this hearing defect. The symptoms of the high-frequency deaf children such as variable reaction to noises, noncomprehension of speech and mutism were due to their subnormal acuity to the usual speech frequencies. Ewing employed special methods of training and education in these patients and was able to produce considerable improvement in hearing and in the ability to acquire new and difficult words by ear alone. The second half of the volume is devoted to an extensive review of the literature of aphasia. The author finds that in proportion to the abundant literature devoted to adults the special treatment of the condition in childhood is relatively small and consists for the most part of a description of word blindness or 'visual aphasia'. As a result of investigations on 100 individuals the author further determined the minimum hearing essential to normal speech and language development in terms of his audiometer readings. Ewing has carried out an important investigation on the study of deafness and aphasia in children and his contribution on high frequency deafness is of the utmost importance. It should be studied in aphasic children as well as those who present symptoms of defective or retarded hearing.

LE DIAGNOSTIC DES ANGINES AIGUES. Par A B Marfan professeur honoraire à la Faculté de médecine de Paris. Paper. Price 10 francs. Pp 92. Paris Masson & Cie 1929.

The purpose of this concise volume on acute sore throat is expressed by the author in his introduction. It is his intention to show first that it is possible by a purely clinical examination to establish enough of a diagnosis to determine whether the case demands antidiphtheria serum and secondly, to make revision in the description and clinical classification of sore throats. As he states the accurate and immediate clinical differentiation is of the greatest importance to the welfare of the patient. It has been the author's experience in diphtheria that when the clinical and bacteriologic diagnosis are based on exact observation there is little discord. There are exceptions in which either a clinical or a bacteriologic examination may be in error, but usually a clinical examination will afford suffi-

cient basis for the diagnosis and, if the case is one of diphtheria, many valuable hours may be saved. For convenience in discussion, he divides the acute sore throats into those in which one does not see a white coating—the red sore throats—and the cases in which there is a more or less extensive membrane—the white sore throats. These two artificial groups are then considered in detail and the various clinical conditions are presented with especial attention to the diagnostic features of each. After a short section on bacteriology, in which it is not his purpose to enter into a full discussion, the author states briefly the conclusions which he thinks are warranted by the preceding exposition. When a pseudomembranous sore throat is primary and does not follow scarlet fever, tonsillitis, syphilis or some other infection it should be considered as diphtheritic and serum should be given at once without delay for bacteriologic examination. When such a pseudomembrane follows another recognized infection, one is justified in regarding diphtheria as improbable, but an immediate bacteriologic examination should be made, as diphtheria does coexist with the other infections. Moreover if an epidemic of diphtheria is present or if there is a laryngitis or a coryza with red nostrils and serous or serosanguineous discharge serum should be given without waiting for bacteriologic results. In any doubtful case that cannot be determined bacteriologically, serum should be used and it should be used in any case in which temporizing might be detrimental to the welfare of the patient, without awaiting bacteriologic observations. The volume has many practical clinical suggestions and is of value and interest.

A PRIMER FOR DIABETIC PATIENTS. A BRIEF OUTLINE OF THE TREATMENT OF DIABETES WITH DIET AND INSULIN. INCLUDING DIRECTIONS AND CHARTS FOR THE USE OF PHYSICIANS IN PLANNING DIET PRESCRIPTIONS. By Russell M Wilder M D Professor and Chairman of the Department of Medicine University of Chicago Clinics. Fourth edition. Cloth Price \$1 50 Pp 138 with 4 illustrations. Philadelphia W B Saunders Company 1930.

Wilder's book fulfils the author's intention to provide a guide for the patient who is under the care of a physician. Believing that no patient with a disease as severe as diabetes should be encouraged to attempt self treatment he expects the patient to secure further guidance and additional interpretation and regulation from a physician. But as a supplementary measure this popular manual other editions of which are now widely used can be well recommended. Perhaps of most practical assistance to the patient will be the seventy-one recipes which do not make use of any unusual or patented ingredients. Equally helpful will be the table of emergency diets designed to meet the needs of the diabetic patient during a period of illness and the simple menu outlines for patients who must travel.

DIÄTETISCHE BEHANDLUNG DER HALTTUBERKULOSE UND ERNÄHRUNG BIOLOGIE. Von Professor Dr Albert Jeuneck und Assistenten Dr Fritz Bernhardt. Tuberkulose Bibliothek. Beiheft zur Zeitschrift für Tuberkulose Nr 3. Herausgegeben von Prof Dr Frida Kalmowitsh. Paper. Price 5 marks. Pp 48 with 24 illustrations. Leipzig Johann Ambrosius Barth 1930.

The beneficial effect of the Sauerbruch Hermannsdorfer Gerson diet on cutaneous tuberculosis is here presented in a concise and beautifully illustrated booklet. The subject matter is divided into two parts. The first part on the Sauerbruch Hermannsdorfer Gerson diet and skin tuberculosis presents discussions of the methods employed diet diet plus minerals phosphorus and cod liver oil and diet plus physical therapy especially ultraviolet radiation. The authors are fully convinced of the real value of the diet alone in clearing up tuberculous lesions of the skin. A chapter on statistics follows giving support to these treatments. Then come two interesting chapters on the evolution of local healing and the effect of the diet on general health and reports on the permanence of the results attained. The first section of the book closes with mention of 4 cases out of the 341 under their control that failed to respond to the treatment and a discussion of technical questions arising from the extended use of diets in tuberculous patients. The second section concerns itself with the rationale of feeding as observed in nature. A study of the structure of cells and unicellular organisms is given and the life of animals and primitive man with their instinctive methods of feeding is given as evidence in support of the rationality of the diet. Civilization and changes in the types of food and diet

of preparation especially concerning the salt content are discussed. Raw foods, the rational feeding of tuberculous patients and a comparison of the Sauerbruch Hermannsdorfer-Gerson diet and natural methods of feeding is made. The brief for the value of the special diet is carefully and conservatively made. On the other hand, mention is made of such dangers as trichinosis, tularemia and pork tapeworm, inherent in the consumption of raw foods. Wide recognition should be given to the methods of treatment discussed in this valuable booklet, especially in sanatoriums, where dietary control is comparatively easy but the diet or an approach to it is not impossible even as a part of home treatment.

A TREATISE ON ORTHOPAEDIC SURGERY. By Royal Whitman, M.D. M.R.C.S. (F.A.C.S.) Consultant to the Hospital for the Ruptured and Crippled, New York. Ninth edition. Cloth. Price \$10 net. Pp. 1085, with 981 illustrations. Philadelphia: Lea & Febiger, 1930.

Whitman's has been one of the standard textbooks on orthopedic surgery for the student, general practitioner and orthopedic surgeon since the first edition in 1901. The text of the present revision contains twenty-four chapters of excellent orthopedic manuscript and illustrations that are well arranged and easily read. One is impressed with the fact that the book is a compilation of years of work and experience with the ultimate attainment of an excellent textbook. In undertaking a revision of his text the author did not bring the statistics down to date except in a few instances. There seems to have been no attempt to modernize the photographic description of various orthopedic conditions. No description is given of several new important features in recent developments in the orthopedic field. There is no mention of the Glikrazzi apparatus in the treatment of scoliosis. Orr's treatment of osteomyelitis is given only one page. There is nothing on Bier's living scavenger treatment for osteomyelitis. Neither Boehler's work on fracture nor Steindler's compensation treatment of scoliosis is mentioned. The chapter on the foot is especially recommended. He has revised the chapters only slightly as follows. For rigid weak foot the operative treatment includes Miller's operation with three illustrations. The operation includes a flap of ligament and bone from the inner side of the foot including the three joints, removing sections from each articulation, correcting the deformity and replacing the flap. Whitman's abduction treatment of fracture of the femur is given and no changes are found except for the addition of Krenz's observations on twenty-three bodies in which he found that the most secure apposition of the fragments is obtained by a position of 45 degrees abduction with inward rotation and extension. It is regrettable that Whitman does not give his own statistics of his results on this method which he popularized. Almost no changes are made in the portion on Whitman's reconstruction operation for ununited fracture of the neck of the femur.

DER OERIERTE MACEN. Von Prof. Dr. Hermann Meyer Burgdorff und Dr. Walter Schmidt. Paper. Price 9.60 marks. Pp. 114 with 146 illustrations. Leipzig: Georg Thieme, 1930.

This will be found of interest to the internist, surgeon and roentgenologist alike. The diversity of symptoms arising following gastric operations require careful investigation. The roentgenologic study of the gastro-intestinal tract after operations on the stomach is difficult because of the anatomic and functional changes it undergoes. This difficulty is exaggerated by the multiplicity and variety of the types of gastric operation as well as the anastomoses used. A thorough understanding of the operative technique is essential to interpret correctly the appearance of the stomach postoperatively and to evaluate its function. The work is based on a clinical and roentgenologic study of 400 postoperative gastric cases. The authors after a preliminary discussion of the normal physiology and morphology of the stomach as well as the effect of disease consider the various possible operations on the stomach. The plan consists of a presentation of the important technical details of each operation, the clinical symptoms that may follow, and their roentgenologic interpretation as well as the difficulties that may arise during the examination and how to avoid them. The subject is discussed clearly and adequately and is the more valuable since it is based on a personal follow-up study of such a large number of cases. Diagrams and roentgenograms

graphically illustrate the many points presented. An excellent bibliography is appended. The monograph is not only interesting but of value to those who deal with medical or surgical gastroenterology, diagnostically or therapeutically.

GENETIC STUDIES OF GENIUS. Edited by Lewis M. Terman. Vol. III. The Promise of Youth. Follow-Up Studies of a Thousand Gifted Children. By Barbara Stoddard Purks, Dortha Williams Jencks and Lewis M. Terman. Assisted by Alice M. Leahy, Helen Marshall and Melita H. Oden. Cloth. Price \$6. Pp. 508. Stanford University Stanford University Press, 1930.

In this volume a thousand gifted children studied over a period of several years are analyzed as to their later development. The children concerned were first located and studied in 1921 and 1922. Since that time their development has been followed regularly with tests of achievement and intellect, and an attempt to determine as nearly as possible the reasons for genius. The first two volumes of this series covered the mental and physical traits of the children and the early mental traits of 300 of them. The present volume provides retests of intellect, a record of educational progress, scholastic and other interests, vocational plans and vocational achievements, social and personality traits, school acceleration by several and personality problems. In their summary, the authors provide a composite picture of a gifted child. They point out that, in the case of such of these gifted children as have grown up and married, the spouses are as a whole less well educated than the gifted subjects that have married them. They feel that something should be done about this, that it is indeed a duty of the gifted to select gifted mates to improve the character of the stock. One of the chief difficulties of eugenics is the fact that it has never yet been successfully capable of overcoming the effects of the biologic urge and the emotions.

MEDIZINISCHE PRAXIS. SAMMLUNG FÜR ARZTLICHE FORTBILDUNG. Herausgegeben von Prof. Dr. L. R. Grote, Chefarzt der C. von Noorden Klinik, Frankfurt a. M. Prof. Dr. A. Fromme, Direktor der chirurgischen Abteilung des Stadtkrankenhauses, Dresden-Friedrichstadt, und Prof. Dr. K. Warnekros, Direktor der staatlichen Frauenklinik zu Dresden, Band IX. Blutung und Thrombose. Von Prof. Dr. Hans Runge, Oberarzt der Universitäts-Frauenklinik Kiel. Mit einem Vorwort von Prof. Dr. Robert Schröder, Direktor der Universitäts-Frauenklinik Kiel. Paper. Price 8 marks. Pp. 108, with 18 illustrations. Dresden: Theodor Steinkopff, 1930.

This monograph is one of a series of eleven prepared for general practitioners. The present monograph contains only material of practical interest and application concerning uterine and cervical bleeding and leukorrhea. The arrangement of the material is ideal for the practitioner, the subject matter is presented in simple, concise language and the few illustrations that are reproduced are most instructive. In order not to confuse the practitioner, the author nearly always describes his own methods of treatment for each condition instead of enumerating the preferences of other authorities. The discussion on hemorrhage takes up eighty-five pages and includes bleeding not only from the uterus and cervix but also from the vagina and vulva. In the first part is a discussion of the physiology of uterine bleeding, including a consideration of the hormones. Then the author takes up the irregularities of menstrual bleeding and finally atypical hemorrhages not associated with the menses. At the end of this section is a chapter on the practical utility of hormone preparations in the treatment of uterine hemorrhage. The discussion on leukorrhea takes up twenty pages and is divided into discharges that arise in the vestibule, the vagina, the cervix, the body of the uterus and the tubes and leukorrhea during pregnancy. The booklet is well worth reading not only by general practitioners but also by specialists in gynecology.

SCIENCE AND THE SCIENTIFIC MIND. By Leo E. Sordla, Assistant Professor of English, Polytechnic Institute of Brooklyn, and Warren E. Giles, Instructor in English, Columbia University. Cloth. Price \$3. Pp. 506. New York: McGraw-Hill Book Company, Inc., 1930.

In this volume are collected some nontechnical scientific articles by twenty-four noted figures in the field of science. They represent the finest type of the essay. They are written by men with a thorough knowledge of the subjects they discuss. The publishers have wisely suggested the possibility that this material might well be used as a model for the scientific writer.

LES URTICAIRES CRISES HÉMOCLASIQUES Par Ldouard Joltrain directeur de l'Institut de recherches de la clinique médicale du Professeur Vidal à l'Hôpital Cochin Avec biographie du Professeur Fernand Vidal Paper Price 40 francs Pp 417 with illustrations Paris G Doin & Cie 1930

In this book, Joltrain an undoubted disciple of Vidal has taken the urticarial syndrome and placed it on a firm foundation. He deals first with the historical background, then with clinical manifestations, and then attacks the etiologic problems. In an enlightening manner he discusses alimentary agents fish, eggs wheat bread and others medicinal agents such as arsenic, bismuth antipyrine and insulin protein and such albuminoid agents as vaccine and hydatid fluid, and physical agencies, as cold, heat and light. Especially interesting is the chapter on the production of urticaria by fatigue. The association of urticaria with asthma, paroxysmal tachycardia, gallstones, eczema, hyperthyroidism, epilepsy, psychoses and other morbid conditions is thoroughly considered in a stimulating chapter. The closing chapters on the humoral changes during an attack of urticaria, the role of the constitutional factors, diagnosis and therapy are excellent. The book closes with a bibliography, which, contrary to the too common continental custom is international in scope. This book recommends itself to the general medical profession but most of all to the dermatologist.

PIERSOL'S HUMAN ANATOMY INCLUDING STRUCTURE AND DEVELOPMENT AND PRACTICAL CONSIDERATIONS By G Carl Huber M.D. Sc.D. Professor of Anatomy University of Michigan Ninth edition Cloth Price \$10 Pp 2104 with 1734 illustrations Philadelphia J B Lippincott Company 1930

The first edition of this book published in 1906 was edited by the professor of anatomy at the University of Pennsylvania Dr George A Piersol, who was assisted by the emeritus professor of surgery and by professors of anatomy of Harvard University, the University of Toronto and Western Reserve University. The present edition has been revised under the supervision of Dr G Carl Huber and several other teachers of anatomy at the University of Michigan. They have introduced a uniform anatomic nomenclature, and sections in the text dealing with the development of the lymphatics and the primary veins, the histogenesis of the blood elements the peripheral nervous system and sections dealing with the fiber paths of the central nervous system. A new anatomy always interests a medical student. The science is fundamental to the study of medicine and the student acquires his knowledge largely by visualization. He must see anatomy with his eyes his microscope and his mind. A great aid to the student in forming these mental pictures is a textbook that is filled with pictures. This book is well illustrated and therefore most helpful to the student. There are many new illustrations printed in a way that makes learning easier. Certain areas of an object are tinted for example, in order that special features may stand out. Many sagittal sections of parts of the body are included to show the relation of the various structures. The illustrations through their excellence, form a special feature of the book.

HANDBUCH DER THEORETISCHEN UND KLINISCHEN (ALLGEMEINEN UND SPEZIELLEN) RÖNTGENKUNDE Herausgegeben von Guido Holzknacht Band II Otologische Röntgendiagnostik Von Dr Ernst G Mayer Assistent am Zentral Röntgeninstitut Professor Dr G Holzknacht Wien Klinischer Beitrag—Die Wertung und Verwendung der Röntgenbefunde in der Otolgie Von Dr Karl Eisinger Assistent und röntgenologischer Referent der Univ Klinik für Ohren Nasen und Kehlkopfkrankheiten Professor Dr H Neumann Wien Paper Price 75 marks Pp 35 with 617 illustrations Vienna Julius Springer 1930

The reading of this volume makes one wish without prejudice to native authors that there were more works of this kind available in our own language. It appears to be a complete and detailed study of the temporal bone in states of health and disease. Roentgen technique is described in detail. An absorbing series of pen and ink illustrations indicate line by line in three standard German positions anatomic points of interest. A careful perusal of this section can hardly fail to be of immense benefit. There are chapters on disease states and fac-similes of actual x-ray films accompanied by pen and ink drawings to illustrate important features. Syphilis and tuberculosis and their x-ray manifestations as well as new growths benign and malignant, tumors fractures postoperative defects and congenital malformations are interestingly dealt with. There is a complete and absorbing discussion of the value and uses of roentgenology in otology by the second author.

VIII THE MOVEMENTS OF THE EYES IN READING By M D Vernon Reports of the Committee upon the Physiology of Vision Medical Research Council Special Report Series No 148 Paper Price 9d Pp 45 London His Majesty's Stationery Office, 1930

This monograph describes experiments made in the psychological laboratory at the University of Cambridge on the movements of the eyes in reading. The author investigated the effects of different factors, such as meaning, interest, and training of thought, on the effector mechanisms of reading, these effects being judged by observation of the ocular movements and the rate of reading. The basis of these experiments is the method originally invented by R Dodge and depends on the fact that the movements of the bright spot of light reflected from the cornea are the same in direction, though only half as great in magnitude, as those of the eyeball itself. These movements were recorded on a continuously moving film by the reflection of a small, strong beam of light, the source of which was a 100 candle power Edison Pointolite bulb which was directed toward the corner while the experimental subjects were reading various types of reading matter. It was proved that the most rapid and regular reading was shown by the mature reader with fairly easy material when he was attending to the content although this may show some modification. It is true that the average rate of reading of all types of material may be determined by training and use, since with one exception it was approximately the same for all subjects of these experiments who had had a similar general education, while it was slower for the subject who had had less education. It was shown that the reading time varies enormously about the mean according to the individual's reactions to the material read. The average duration and frequency of the fixation pauses together constituted the average reading time. The relation of duration to frequency was shown to be in all probability a function of the motor ability and accuracy of the subject's extra ocular muscles. No connection with actual ocular defect was established, but it is possible that there may be some variation of motor skill apart from any defect that can be diagnosed. The author concludes that the rate of reading varies enormously according to a variety of mental processes, unconnected with training which accompany reading, and of which conative impulses may possibly be the most fundamental. The article is more definitely related to the psychology of vision than to its ophthalmologic aspects but may well be read with interest by every ophthalmologist.

DER CHIRURGISCHE OPERATIONSKURSUS EIN HANDBUCH FÜR ARZTE UND STUDIERENDE Von Prof Dr Victor Schmieden o.o Professor der Chirurgie Direktor der chirurgischen Universitätsklinik zu Frankfurt a M und Prof Dr A W Fischer Oberarzt der chirurgischen Universitätsklinik zu Frankfurt a M Twelfth edition Cloth Price 48 mark Pp 543 with 586 illustrations Leipzig Johann Ambrosius Barth 1930

This deals principally with the fundamentals of surgery. It is an extremely popular book in German schools and information from German surgeons discloses that it is a necessary textbook for the German medical student in that his examinations in surgery are based on his knowledge of its contents. Surgical anatomy and the fundamental principles of surgical technique are taught with reference to this book as the textbook. This in itself proves its value. Aside from being a textbook it is also of great value as a work of reference. The arteries or blood vessels nerves and tendons the technique of amputation and radical resections of important structures as in the case of cancer are beautifully illustrated with colored drawings. In fact the illustrations are one of the principal assets of the book. The type and use of instruments in the various operations are clearly described and illustrated the same as in an instrument catalogue. There are numerous illustrations showing the exact technique of all the operations that are described. The author has developed these features in a clear simple direct and concise style.

DICTIONARY OF BIOLOGICAL EQUIVALENTS (FRENCH-ENGLISH) By Ernst Arschwager pathologist Bureau of Plant Industry U.S. Department of Agriculture Cloth Price \$4.50 Pp 252 with 76 illustrations Baltimore Williams & Wilkins Company 1930

In this volume the German terms frequently used in scientific literature are given their English equivalent. The source of the words is the publication *Biological Abstract*. The volume is useful.

Medicolegal

Right of Medical Society to Expel Members

(*Irwin Lorio et al and three other cases (La) 176 So 669*)

The Stranicola Employees Medical and Hospital Association, an association of the employees of a certain corporation to procure medical and hospital services for its members contracted with Drs Irwin Young and Morris to furnish such services. The physicians named were members of the East Baton Rouge Parish Medical Society which is chartered by the Louisiana State Medical Society and is bound as is the state society by the code of ethics of the American Medical Association. One provision in this code reads in part, as follows:

It is unprofessional for a physician to dispose of his services under conditions which interfere with reasonable competition among the physicians of a community.

An expulsion from the local society acts as an expulsion from the state society. Because of this the by-laws of the state society give any physician expelled from or refused membership in a local society the right to appeal to the council and house of delegates of the state organization.

The local society adopted a resolution that any member failing to comply with the section of the code of ethics set forth should be deemed no longer to desire membership in the local society. At a later meeting at which a quorum was present the local society declared by resolution that the contracts between the physicians named and the association were unethical. Thereafter an opportunity was given the physicians to surrender their contracts which they refused to do. The society then instituted proceedings to expel them. The physicians named and the hospital association individually brought court actions against thirty physician members of the society a majority of the membership to restrain them from expelling or voting to expel the complaining physicians. The contracts the complainants alleged, were not in violation of the code of medical ethics the expulsion of the physicians would deprive them of the right to use the only hospitals in the community, since the hospital management would permit only physician members of the local society to use their hospital facilities the use of the hospitals was necessary in the practice of the complainants and in discharging their contracts which constituted a valuable property right and the physician defendants had conspired to expel them from the society. A temporary injunction was granted, and the defendants appealed to the Supreme Court of Louisiana.

A local medical society said the Supreme Court of Louisiana, has the power to suspend or expel its members for legal cause, after determining from a due hearing had whether the cause alleged for suspension or expulsion has been established. After the final hearing, the member proceeded against has the right, given him by the local and the state society, to appeal to the council and the house of delegates of the latter, where the fairness of the trial may be looked into and the order of suspension may be annulled or affirmed as justice may demand. Since the appeal allowed by the by-laws of the two societies is an effective appeal—that is one which would prevent the local society from carrying out its order of expulsion until the appeal is passed on—the person aggrieved must exhaust his recourse within the society before he may resort to the courts. In 5 C J 1364, it is said:

The courts will not interfere with the internal affairs of an unincorporated association so as to settle disputes between the members or questions of policy discipline or internal government so long as the government of the society is fairly and honestly administered in conformity with its laws and the law of the land and no property or civil rights are invaded. Conversely the proceedings of the association are subject to judicial review where there is fraud oppression or bad faith or property or civil rights are involved or the proceedings in question are violative of the laws of the society or the law of the land or are illegal. Even in the case however the courts will not take jurisdiction unless the complaining member has exhausted such remedies as may be provided by the laws of the association itself.

The rule that a complaining member of a voluntary association must exhaust his remedies within the association before he may resort to the courts for relief has been recognized by this court in *Robb v Trecklin* 122 La 174, 47 So 455, and *Braden v*

Leavis 148 La 920, 88 So 117. In the instant case the complaining physicians have not exhausted their remedy within the society.

While said the Supreme Court, it is true that the injunction here prayed for is not directed against the association itself or all of its members the injunction is directed against a majority of the members. To restrain them from voting on charges preferred for the expulsion of a member is the same in effect as though the association or its entire membership had been restrained for the right of the association to function is thereby greatly interfered with, if not entirely destroyed. The principles quoted are therefore applicable to the present situation.

The injunctions issued by the lower court were accordingly dissolved and the local medical society was left free to proceed with the hearings.

"Patent Medicine" Defined—The article compounded and vended by the appellant was prepared from a secret formula as a medicine for the treatment of certain diseases, put up in packages or bottles and labeled with a name for immediate use. This was sufficient to constitute it a patent medicine in the sense in which that term is generally used and in which it was used in the city ordinance under which the question arose. While originally the word 'patent' was attached to an article because it was the subject of a patent, it has lost that significance by usage and has become merely a part of the name of the article. Where any article intended to be used for medicinal purposes is prepared from a secret formula and is placed in containers, either packages or bottles, for sale to be used without further preparation and is labeled so that it may be for immediate use it is a matter of common knowledge that such remedies are 'patent' or 'proprietary' medicines.—*Riggs v City of Hot Springs* (41) 26 S W (2d) 70.

Insurance Gonorrheal Rheumatism a "Serious Disease"—An insurance policy provided, among other things, that it was void if the insured, within two years from the date of its issue had attended a hospital or had treatment by a physician for any serious disease, complaint or operation. It was conceded that within the period named, the insured was in a hospital for eighty-five days, undergoing treatment for gonorrheal rheumatism. The Supreme Court of New York, Appellate Division, First Department on appeal held that the insured had a serious disease within the meaning of the policy.—*Buller v John Hancock Mut Life Ins Co* 240 N Y S 328.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL in continental United States and Canada for a period of three days. Issues of periodicals are kept on file for a period of five years only. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

- Case of Fetal Generalized Edema J J Gill and I Auld, Chicago—p 834

Survey of Causative Factors in Sterility—Meaker reports some of the results of an organized group study conducted during the past three years. He discusses absolute and relative sterility. In absolute sterility the initiation of the reproductive process is, at any rate for the time being, flatly impossible. This situation results from conditions of two general sorts: those suppressing entirely the production of ova or spermatozoa, and those entirely preventing the access of spermatozoon to ovum. Such disability may be temporary only and remediable by nature or art, or it may be permanent. Absolute sterility is found in about 30 per cent of sterile matings. In relative sterility, on the other hand, the initiation of the reproductive process is not definitely impossible but is to some extent impeded and made difficult. Ova and spermatozoa are produced but they may be deficient in number and subnormal in quality. The access of the male gamete to the female is not entirely prevented, but obstacles of one sort or another may be placed in the way. Thus the capacity for reproduction, still actually present, is diminished to a degree that varies within wide limits in different cases and fluctuates within narrower limits in the same case at different times. Sterility is commonly due to the combined influence of multiple causative factors. Any single one of these excepting the comparatively few absolute factors may not be sufficient to cause sterility; all of them together depress fertility below the threshold of conception. About one third of all demonstrable causative factors are extragenital conditions of constitutional depression, which lower the inherent fertility of the gametes. Such conditions are operative, in one or both partners, in nearly 90 per cent of sterile matings. In the male they are in the aggregate more important than abnormal local conditions. About one third of all demonstrable causative factors are on the male side and two thirds on the female side. In more than 90 per cent of clinical case, however, there is some division of responsibility between the two partners. Complete investigation points the way to adequate treatment which in the author's cases has thus far yielded a percentage of successful results more than twice as great as the average of successes obtained by former methods.

Acriflavine Intravenously in Experimental Uterine Infection—The experiments reported by Meyer show that the

intravenous injection of an appropriate dose of acriflavine hydrochloride has a definite beneficial effect on the course of the experimentally infected uterus of the dog. The earlier the dye is injected, the more definite the effect. In some instances, sterile cultures of the inoculated or infected uterine horn are obtained after acriflavine therapy. The beneficial effect of the acriflavine on the course of the uterine infection is also shown by the return to normal in body temperature by lysis. On the basis of these results it is believed that intravenous acriflavine in appropriate dosage is worthy of being tried in early uterine infections.

Method of Delivery in Occiput Posterior Position—Vaux is convinced that prenatal care of the mother with regard to the toxemias and antenatal health of the individual has so overshadowed some of the equally important conditions existing in these women that the subject of pelvic abnormalities and positions prior to delivery has been greatly neglected. He insists that the diagnosis of position should be made before labor onset if possible and definitely established as early as possible after the onset of labor. The primiparous patient with a moderately contracted pelvis should be looked on before the onset of labor as resulting in the possibility of a posterior position existing, with a difficult labor ahead. The aim of conserving the amniotic sac intact, and guarding more carefully the patient's strength during the long first stage of labor in posterior position cases, is of paramount importance in whatever method of delivery is selected. Intervention is not justified in posterior positions until the cervix is fully dilated and effaced and until the fetal head is at or near midpelvis.

Carbon Dioxide Content of Blood in New-Born—The carbon dioxide content of the blood of forty-seven new-born infants was determined by Kane and Kreiselman. The forty-seven specimens examined were divided into three groups: blood (1) from babies deep in asphyxia, (2) from babies who gasped once or twice during the collection of the blood, and (3) from babies who were born crying. It would seem that the carbon dioxide content of the blood in the new-born is consistently high, that the proportion of carbon dioxide increases with the degree of asphyxia, and, therefore, that the addition of carbon dioxide to oxygen as a resuscitating agent is contraindicated.

Relationship of Tuberculous Cervical Adenitis to Pulmonary Tuberculosis—Grabfield and Miller are of the opinion that the correlation between thickening of the apical pleura and tuberculosis of the tonsils and cervical lymphatics is too close to be a matter of chance, and consequently one must take into account the possibility of this path of infection in pulmonary tuberculosis

Tuberculous Infection in School Children—This study by Chidwick and Zacks is based on 42,071 children examined and given the Pirquet tuberculin test during a period of three years. The ratio of reactors in the 42,000 children studied in this series shows a gradual trend upward from 21 per cent infections at age 5, and 28 per cent at age 10, to 35 per cent at age 15. The average percentage for the whole group is 28. Different sections in the same city may show a wide variation in the percentage of reactors. It was found in one city of 60,000 that the number of children reacting to the tuberculin test in different school districts varied from 11 to 60 per cent. The number of reactors increases with the opportunities that the child has for contact with bacillus carriers. Persons with chronic forms of pulmonary tuberculosis, such as are found in granite quarry workers, expose and infect more children than persons with the more acute forms, who live a much shorter time after the disease becomes infectious. Crowded living conditions afford more opportunities for contact and congested areas show a higher percentage of infection. Twice as many reactors are found among children with a history of direct contact with a case of pulmonary tuberculosis. Another factor to be taken into account is bovine infection. In a few rural towns with a scattered population and less than the average number of pulmonary tuberculosis deaths, 38 per cent of reactors were found. The majority of the small towns however, show a little less than the average percentage for the state as a whole. The boys of the Irish Canadian and Teutonic groups in this series show a much higher incidence of infection than the girls. The death rate in Massachusetts for all forms of tuberculosis declined from 144 per hundred thousand in 1917 to 73 in 1927. Three important factors have operated to bring about a reduction in the number of infected children. 1 The steady decline in the death rate results in fewer persons with tuberculosis at large in the community to spread infection. 2 The state has a little more than one bed for each tuberculosis death in which to segregate cases of tuberculosis and so further reduce the foci of infection in the homes of these patients. 3 Pasteurized milk is now available for about 60 per cent of the population of the state and by so much is the possibility of bovine infection curtailed.

Oleothonax Olive Oil in Pulmonary Tuberculosis—Sillig and Lang assert that oleothonax if judiciously applied is a useful adjunct in the treatment of certain complications of pulmonary tuberculosis and if carefully done, is not dan-

gerous to the patient. In one case of spontaneous pneumothorax reported, the treatment appears to have prolonged the life of the patient.

Thoracoplasty in Chronic Pulmonary Tuberculosis—Bruns and Casper have performed 210 thoracoplastic operations on 120 different patients and for statistical purposes have divided the patients into groups—those operated on from 1922 to 1928, inclusive, which demonstrate more the end results, and those in 1929 and 1930, showing more the immediate effects of thoracoplasty. Among the 1922 to 1928 group, eight (8.6 per cent) operative deaths occurred, as compared with no operative deaths in 1929 and two so far in 1930. This is probably due to greater care in selecting cases, improved operative technique and better adjustment of the extent of the operation to the patient's condition. Twenty six are apparently cured, twenty-three are arrested, nineteen are improved, seven are unimproved, and forty five died.

Radical Phrenicotomy—Aycock and Habliston dissected 130 phrenic nerves in the anatomic laboratory. Approximately 65 per cent of phrenic nerves in this series either showed anomalies or received accessory fibers below the usual site of operation. To insure the maximum beneficial results that should attend hemidiaphragmatic paralysis, phrenico-exeresis should be performed rather than simple phrenicotomy. It is of the utmost importance to remove at least 11 cm of the distal portion of the nerve in order to insure the desired result.

Phrenico-Exeresis in Pulmonary Tuberculosis—Cooper regards phrenico-exeresis as a valuable procedure in selected cases of mainly unilateral pulmonary tuberculosis, and it may be of possible benefit in bronchiectasis, also, that even some involvement of the contralateral lung with small cavitation is not in itself a definite contraindication. This operation if there is a successful result definitely tends to put the side operated on at rest. The operation in itself is a rather minor one and can be performed as a rule under local anesthesia. It has been found to be useful in particular cases in which there were pleuritic adhesions which prevented the administration of pneumothorax, and, if successful, it not only lessens the motion of the diaphragm and thus the respiratory excursion on the operated side but causes a definite partial collapse of the lung. The operation may be even of benefit to lesions of the upper lobe, as it appears that the operation in itself may not tend primarily to cause a collapse of the less involved part of the lung but may cause rather a greater collapse of the diseased portion. The less diseased lung if disease is in the base may not tend to collapse following such operation if the more diseased portion of the lung is in the apex. If the less diseased portion is in the base of the lung this part tends to move upward *en masse* in many cases, tending to compress an upper diseased portion.

Conditions Affecting Clinical Excretion of Bismuth—The effects of water drinking and of thermal, mechanical and chemical measures on the clinical urinary excretion of bismuth were investigated by Hanzlik and Mehrtens in subjects possessing gluteal depots of bismuth metal. The excretion of bismuth and diuresis varied directly with the changes in water intake. Of the four thermal measures tried, all of which increased the body temperature steam baths and injections of typhoid vaccine increased the excretion of bismuth, though variably, in the majority of subjects used. Tub baths gave

equivalent results, and malarial fever was ineffective. A mechanical device that increased the muscular activity in the gluteal regions caused moderate increases in bismuth excretion in two of three subjects. The chemical measures tried were the chloride, iodide, thiocyanate, thiosulphate and bicarbonate of sodium and ammonium chloride, all given orally, except thiosulphate, which was given intravenously. Increases in the excretion of bismuth in the majority of subjects tested were caused by chloride, iodide and thiosulphate, and in half of the subjects by thiocyanate, while ammonium chloride and sodium bicarbonate gave variable or ineffective results. The increases in bismuth excretion, when present, were not necessarily related to increased diuresis, the urine output being often decreased, though frequently variable, among the groups of subjects receiving the different measures. It appears that certain measures might be employed for increasing the excretion of bismuth, as in poisoning, and for mobilization of tissue bismuth in promoting therapy of syphilis. The simplest, most convenient and economical measures would be the liberal drinking of water and the use of ordinary salt (sodium chloride) in conjunction with the dietary. Various possibilities are discussed.

Treatment of Staphylococcal Infections of Skin by the Bacteriophage—The result of treatment of fifty-seven patients with staphylococcal infections are reported by Crutchfield and Stout. The clinical results are shown to be much better than in similar cases in which other means of treatment were used. Results cannot be obtained without a bacteriophage that is capable of lysing the infecting organism and transmitting such power.

Tribrom-Ethanol Anesthesia—Waters and Muehlberger record their experiences with the clinical administration of this drug in 100 cases. The patients represented a wide range of surgical risks. No advantage appears to result from the use of tribrom ethanol fluid (67 per cent tribrom ethanol plus 33 per cent amylene hydrate) in place of crystalline tribrom ethanol for the preparation of anesthetic solutions. The crystalline form of the drug gave more satisfactory results than the amylene hydrate solution. Details of the use of this drug are discussed fully. The authors find justification for the addition of tribrom ethanol to the present well recognized list of anesthetic drugs.

Skeletal Metastases from Carcinoma of Rectum—Eight cases of rectal carcinoma complicated by skeletal metastases are reported by Aufses. In the main the site of the metastases conforms to the original table of frequency as stated by von

Recklinghausen. Metastases to the bone in carcinoma of the rectum occurs late in the course of the disease, but with sufficient frequency to make it of clinical significance and to make its early diagnosis of great importance in relief from pain and the prevention of fractures.

Value of Drugs in Relief of Ileus—The results obtained by Ochsner et al appear to be in line with those obtained by the more careful and unprejudiced experimental investigators who have previously published reports on the action of pituitary extract. Pituitary extract would not only seem to be an ineffective drug in the treatment for intestinal atony but also would appear to be a dangerous drug in such a condition. The effect of physostigmine on the intestinal tone and motility, according to their investigations, is virtually that which might be expected from a consideration of previous reports, both clinical and experimental. This is the only drug that they have found to be of consistent efficacy, and the fact is stressed that the action of this drug seems to be enhanced in intestinal obstruction at least in intestinal obstruction no further advanced than that used for the purposes of the present experimental investigation. Choline, acetylcholine, pitocin and peristaltin have proved disappointing. Apparently little dependence can be placed on these therapeutic agencies in the stimulation of either normal or hyperexcitable intestinal musculature. All in all, it would seem that the drug therapy for intestinal atony rests on a rather precarious foundation, and although the results of these experimental investigations are by no means conclusive, they suggest a well nigh complete revision of evaluation of the efficacy of drug therapy in the relief of conditions of intestinal quiescence.

Gastropasty of Lesser Curvature—The method of gastropasty described here is brought forward by Armour to avoid the possibility of interfering with the motor mechanism of the lesser curvature. It is offered as a possible treatment for lesser curvature and posterior wall ulcer (penetrating posteriorly) as a substitute for the present day more radical partial gastrectomy, the stomach being left fixed to its bed.

Retroadisplacement of Uterus and Its Correction—Abbott describes an operation that he has employed successfully in eight-seven cases. It consists of the transplantation of the round ligament together with the plication of a considerable portion of the broad ligament, this structure being used to help support the uterus.

Bactericidal Effects of High Frequency Sound Waves

—Williams and Gaines have made a study of the lethal effects of supersonic waves on bacteria. It has been possible to kill cells of *Escherichia coli* by exposure in liquid to high frequency audible sound waves of about 8,800 cycles per second. The lethal effects are probably due to a violent agitation set up within the cell by these waves. Lytic action on red blood corpuscles has been observed.

Human Carriers of Streptococcus Epidemicus—Pilot

et al. assert that *Streptococcus epidemicus* is found in the throats of persons during interepidemic periods. The chief habitat appears to be the crypts of the faucial tonsils. Three carriers of *S. epidemicus* had enlarged tonsils, cervical adenitis and arthritic pains. The recognition of these carriers is important because of their possible role in the transmission of the disease to others and particularly in the accidental infection of the udder of the cow, with subsequent explosive epidemic sore throat spread through the milk.

Herpes Encephalitis in Monkeys of Genus Cebus—

Herpetetic encephalitis has been produced by McKinley and Douglas in five of nine monkeys of the genus *Cebus*. The disease in its acute and subacute form closely resembles human encephalitis. The pathologic lesions are also similar to those of the human malady except for the presence of intranuclear herpetetic inclusion bodies in the ganglion cells of the cortex. The disease kills *Cebus* monkeys in from six to eleven days. Secondary invading streptococci were demonstrated in the brain of one monkey. Healthy monkeys receiving an emulsion of the brain of this monkey did not show any streptococci either on cultivation of the brain or on inoculation of it in rabbits. These studies indicate that the green streptococcus is not related to the virus infection in question but that this microbe may, in

occasional animals under optimal conditions, invade the central nervous system after the "soil" has been previously prepared by the virus. The authors therefore see no reason for attaching an etiologic relationship to the green streptococcus in such a disease as encephalitis.

Untoward Results in Bilateral Pyelography—Five cases are reported by Shapiro and Veseen in which death supervened after and directly ascribable to cystoscopic examinations in which bilateral pyelography was carried out. The mediums used were thorium nitrate 15 per cent, two cases, sodium bromide 25 per cent, one case, sodium iodide 12.5 per cent, two cases. Four postmortem examinations were made. In two cases extensive infection had supervened. In the other two, and probably also in the case in which a postmortem was not done, the cause of death seemed to be the toxic action of the pyelographic medium. The authors contend that pyelography is a diagnostic procedure and as such should not be associated with any mortality. They therefore advocate unilateral pyelography.

Metastatic Abscesses of Genito-Urinary Tract—The case of metastatic abscesses of the genito urinary tract cited by Fish required a nephrectomy, two nephrotomies, and drainage of a prostatic and of a peri urethral abscess. Perhaps the most interesting feature of the case is that the abscesses were confined to the urinary tract. There was destruction of at least half of the remaining kidney but the patient made a good recovery. He entirely regained his weight returned to rather hard work in the country had a normal blood urea and clear urine, and was in all respects a well man.

Isocaine as Urethral Anesthetic—Hager and Loevenhart are of the opinion that the degree of anesthesia obtained with isocaine compares favorably with that obtained with the use of cocaine. A 1 or 2 per cent solution of isocaine appears to be adequate to permit of satisfactory urethral instrumentation. The satisfactory anesthesia coupled with the lessened toxicity isocaine being three tenths as toxic as cocaine, indicates a high therapeutic index for isocaine as a surface anesthetic for the urethral mucosa.

Military Lung Disease Due to Unknown Cause—Sayers and Meriwether report the work done in a clinic established at Picher, Okla for the study and control of silicosis and tuberculosis among the miners. Physical examination including roentgen examination of the chest, is made of the men prior to employment and at least once yearly thereafter. A total of 18,285 individuals had been examined up to and including December 1929. About 125 cases of typical military lung disease were found by roentgen examination among these 18,285 individuals during routine physical examination. A majority of the affected persons did not have sufficient symptoms to cause them to stop work or to seek medical aid. The most characteristic finding was a large number of discrete, dense, shottile spots scattered over the lung areas. Tubercle bacilli were present in only two of the eighty-eight cases in which an examination was made of the sputum. Unstained smears of thirty-one cases (all those examined) were positive for fungi. Two types of fungi were identified—*Aspergillus fumigatus fischeri* and *Aspergillus niger*. Ten cases tested with antigen of *Aspergillus fumigatus fischeri* gave negative reactions, six cases tested with *Aspergillus niger* all gave positive reaction. The authors are of the opinion that thirty-eight cases reported by Sutherland as presenting military calcification of the lungs are probably instances of the same condition that was found at Picher. In addition they suggest that these military calcifications may be due primarily to fungous infection.

Intravenous Cholecystography and Determination of Liver Function—Although it is clearly recognized by Miller and Waters that their series of 131 cases is a small number on which to base any positive conclusions, they feel that the evidence produced is of value so far as it strengthens the weight of opinion in favor of intravenous, as compared with oral cholecystography. The dye has been found comparatively non-toxic, since few disagreeable reactions have been encountered and none of them of an at all alarming nature. The procedure is not technically difficult or particularly time consuming, three injections being readily given within the space of an hour in a private office. The cholecystograms are unquestionably far superior to those obtained very often after oral administration of the dye. Even though the intravenous method is admittedly the superior one, it is probably true that its uniform adoption will be slow. The method, simple as it is, should in no sense be exploited by those not thoroughly proficient in the technique of intravenous therapy. At least it can be asserted that no internist can accept the report "gallbladder not visualized" as conclusive roentgen evidence of disease of the biliary tract when such films have been obtained following oral administration of the dye. Confirmation or denial of such a report, following intravenous injections, is mandatory, particularly when the clinical picture of gallbladder disease is by no means clear.

Treatment of Hemorrhoids—Pruitt stresses the point that since there are many types of piles no one method of treatment is suitable for all cases. Each patient should be given sufficient examination to determine the type of the pile present. The type of treatment should be based on observations resulting from the complete examination of the individual case and not on the patient's diagnosis. It should not consist of a prescription for an ointment as is customary with many busy physicians.

Treatment of Anemias of Infancy—Josephs feels that medicinal iron given in sufficiently large amounts has a greater effect in raising hemoglobin than food iron. The results with copper as a supplement to iron are highly suggestive. Little need be expected from the use of copper and iron in premature babies and during the course of an infection. In regard to liver as a supplement to iron it has succeeded where copper has failed but on the other hand liver over a prolonged period of time is disagreeable for older children and somewhat expensive and it would be quite satisfactory if copper should prove of value as an efficient adjunct to iron in the treatment of anemia.

Distinction Between Appendical Allergy and Appendicitis—Data presented by McIntosh support the concept of the existence of appendical allergy and suggest its incidence among 310 surgically removed appendices.

 Placental Hormones J. R. Collip —p. 1080
 *Clinical Use of Certain Placental Extracts A. D. Campbell and J. B. Collip —p. 1081

Symptoms and Pathogenesis of Hemorrhagic Diathesis

—Tidy asserts that the hemorrhages in the hemorrhagic diathesis are primarily due to increased permeability of the capillary endothelium. Blood platelets normally protect the capillary endothelium, and the diminution in number observed in the hemorrhagic diathesis is secondary to this action. Escape of plasma from the vessels accounts for certain of the symptoms, especially abdominal colic. Hemorrhages from a single site—for example, hematuria—may occur. There is no constant characteristic change in the blood cells.

Clinical use of Certain Placental Extracts

—The observations reported by Campbell and Collip deal in the main with the possible therapeutic value of the 85 per cent alcohol soluble fraction. A few clinical experiments with the so-called anterior pituitary-like fraction of the placental extract (85 per cent alcohol precipitate) are included. One hundred and twenty-three cases of deranged ovarian function as judged clinically have been treated and observed for periods varying from three to nine months. All the patients investigated were apparently normal individuals, and pelvic examination did not reveal gross or obvious pathologic conditions in the conformation or size of the uterus or its adnexa. A dose corresponding to 75 Gm of placenta daily, given in divided doses in water or orange juice before meals, has been used in the majority of cases. There are individuals who do not tolerate the extract well. In any case in which untoward symptoms, such as nausea or vertigo, have been observed, the dose has been temporarily reduced until tolerance was acquired. According to their experience the use of this extract does not seem to have any untoward effect on impregnation and gestation. It is worthy of note that four patients became pregnant while under treatment for ovarian dysfunction. From thirty-six to forty-eight hours after the institution of therapy, some patients volunteered that they experienced a feeling of general well being and of mental alertness. No effect on libido was reported. As controls, ten women with normal menstrual cycles were submitted to treatment for three months without any alteration being noted either in the length of the interval or in the duration of the epoch. The dosage used in cases of dysmenorrhea was as a rule, the equivalent of 25 Gm of placenta administered daily for approximately seventeen days, beginning with the cessation of a menstrual period. During the week preceding menstruation (twentieth to twenty-eighth day) the dose was raised to 75 Gm daily, and treatment was continued until the onset of the flow and then stopped for a period of about a week. Other individuals with normal cycles obtained relief when treated for seven days preceding the anticipated period. The second principle (85 per cent alcohol precipitate, or the anterior pituitary-like substance of placenta) was employed in metrorrhagia. The results in this small group of cases have been most encouraging. The extract used in these cases contained approximately 10 rat units per cubic centimeter and was administered subcutaneously. No enlargement of breasts or milk secretion occurred with the administration of this hormone. It should be noted here that the diagnosis is essential and that uterine exploration should always precede the treatment.

Convalescent Serum in Prophylaxis of Measles

—Nabarro and Signy report their experiences in this field.

Originally they used 3 cc for children up to 3 years and 5 cc for children over 3. This has never been strictly adhered to, as they increase the dose for big children and for adults, and also if the incubation is well advanced. They have now increased the doses to 5 and 7 cc and believe that this is a more adequate and satisfactory dosage. All the injections are made intramuscularly into the buttock. Serum has been tried in treatment of severe measles without success, because the antibody content is not sufficiently high and enormous doses would be required to have any effect. For the same reason the serum is of no value for the blanching of a rash although it is sufficiently strong to prevent the appearance of the rash in an area if injected before the rash appears generally (Debre's phenomenon). Whole blood may be used instead of serum, and in this case the blood of a convalescent patient is injected intramuscularly into the recipient, the dose being double the serum dose. They have injected serum in 586 cases of which 461 injections were made at the Children's Hospital following ward infections and 125 were cases from practitioners in various parts of the country following home or hospital infections. In the hospital series there were 14 failures, or 3 per cent, and the outside cases 7 failures, or 5.6 per cent. The "failures" in both series include several injected after the fifth day, and are almost all extremely mild cases.

Chronic Appendicitis—Chandler asserts that, if a correct diagnosis has been made, appendectomy should result in a complete cure of every case of chronic appendicitis. The most reliable proof of the accuracy of the diagnosis is the end-result record. The patient who is promptly and permanently relieved following a simple appendectomy did have appendicitis and the patient who is not cured following the operation probably did not have an appendix which was responsible for his complaints. Thus the burden of responsibility is placed on the diagnosis.

Chronic Cholecystitis—A routine study made by King of a number of cases of chronic cholecystitis reveals a remarkable degree of proliferation of the epithelium of the organ. Epithelial structures are found frequently in the muscular and subperitoneal coats. The characteristic form is the glands of Luschka. The proliferation may cause macroscopic thickening of the wall and resemblance to carcinoma, a condition described as cholecystitis cystica. Definite features distinguish it from carcinoma. Interesting changes in the epithelium occur in a proportion of cases with the formation of mucous glands and glands resembling the glands of the pylorus and the glands of Brunner. Squamous epithelium is rare in the gallbladder (though found in two cases of this series), but squamous carcinoma is not very uncommon. Carcinoma was found in fifteen cases of those examined (6 per cent).

Accessory Lingual Thyroid—Willis describes a case in which a latent primary carcinoma of the base of the tongue produced massive cervical metastases diagnosed as 'brancio-genic carcinoma'. These metastases destroyed the thyroid gland. Adequate compensatory enlargement then occurred of a lingual thyroid that had been previously unsuspected which drew attention to the 'latent' primary carcinoma in the same situation.

Treatment of Lobar Pneumonia by Felton's Serum—On the basis of clinical experience, Cowan et al commend Felton's serum as an addition to the other agents used in the treatment of pneumonia. Felton's serum is active only against infections of types I and II, it has no therapeutic value in type III and group V infections. Of the fifteen type I infections one patient died, of the twenty-six type II, two patients, of the type III, the only patient of the thirteen group V infections, two patients. The mortality among 856 untyped cases treated without serum up to 1930 was 18.46 per cent. The mortality of typed serum treated cases (in 1930) was 10.3 per cent.

Lobar Pneumonia Treatment by Concentrated Antiserum—The evidence submitted in this report suggests that the administration of Felton's concentrated antiserum is of distinct benefit in the treatment of lobar pneumonia due to organisms of types I and II. Its action appears to be greater in the case of type I pneumonias. The records show that there were fewer deaths among the patients who received serum. Serum treatment seems to lessen the severity of the disease and undoubtedly shortens the febrile period in a proportion of cases. Many patients appeared to become less ill and more comfortable as a result of the injections. Anaphylactic phenomena were observed in two patients after the first dose of serum, although in both cases the preliminary eye test was negative.

Acute Myelogenous Leukemia—Easton suggests that in cases of acute leukemia the infection is a virulent one—in two cases hemolytic streptococci were isolated—and that the individual has strong powers of resistance to begin with but that it is in the great majority of cases overcome in the end. The fact that it commonly attacks healthy young men would support this. That every case of acute leukemia is due to an infection is difficult to imagine, far more so to prove, but Easton suggests that this causation is more frequent than is generally supposed.

Approaching Appendix Through Transverse Incision—The incision made by Cokkinis is absolutely horizontal and extends from the superior anterior iliac spine inward for 1½ to 3 inches, according to the age and build of the patient. The external oblique aponeurosis is exposed and is split in the line of the skin incision and the muscular fibers of the internal oblique are exposed. These fibers are here running almost transversely and a line of separation is made with a blunt instrument. The transversalis is then split in a similar manner and the transversalis fascia divided in the same direction. The peritoneum is now exposed and at the outer angle of the wound this can be seen coming off the iliac fossa to the anterior abdominal wall in the form of a lateral reflection which stands out as a definite fold. It is picked up and incised horizontally, a 1½ inch opening usually being sufficient. The cecum will be found immediately under the wound and can be delivered easily, except when anchored by adhesions. An adherent subcecal

retrocecal, retrocolic or ileac appendix can be freed and brought out with greater ease than through the more medial oblique or vertical incisions in common use. In the presence of a localized abscess, shut off from the general peritoneal cavity, the incision extends from 1½ to 2 inches inward from the superior anterior spine. After the aponeurosis has been divided and the muscles have been split, the reflection of peritoneum coming off the iliac fossa is sought and peeled inward off the iliacus until the abscess can be felt from behind. It is then opened with the finger or with sinus forceps and cleaned out with swabs on holders. A drainage tube is inserted into the abscess cavity and brought out through the outer end of the wound. With the patient lying a little over on the right side excellent drainage is provided. In this way all danger of soiling the peritoneum is avoided.

Vitamin D in Parathyroid Deficiency Following Thyroidectomy—Subsequent to thyroidectomy or to excessive radiotherapy to the thyroid gland, the following symptoms may develop as a manifestation of parathyroid imbalance: tetany, cramps, numbness, tingling sensation, a feeling of "pins and needles," grave depression, pronounced irritability, cravings for food, excessive appetite, marked gain in weight, pallor, and undue fatigue. Control experiments definitely rule out the possibility of these symptoms being due to hypothyroidism. Hausman states that all these symptoms disappear on the administration of relatively large doses of viosterol. Six cases are recorded which illustrate the response to vitamin D.

Tuberculous Morbidity and Mortality Among House Contacts of Sputum Positive Cases in North Worcestershire—Turner outlines the actual results of tuberculous infection in sputum positive households in a certain geographic area with a population of 160,000. Evidence is produced to establish the fact that house contacts of sputum positive cases of phthisis suffer both an incidence rate of and a death rate from tuberculosis significantly greater at all ages than the corresponding rates for the general population. In view of these facts it is strongly urged that from the point of view of tuberculosis schemes all contacts of sputum positive cases are themselves potential cases of tuberculosis. For this reason it is essential

that they should be periodically examined. Such examination is, in itself, not of great value, unless on the first signs or symptoms of loss of health (which cannot be diagnosed as some other definite clinical condition) the contact can be given a proper course of the appropriate treatment. The author advocates that powers should be given to make preventive treatment available for the contacts of sputum-positive cases, before the contact has reached the stage of being 'notifiable' according to the generally accepted standards.

Severe Hemorrhages in Typhoid Checked by Blood Transfusion.—Audibert et al report a case of severe hemorrhage in the course of typhoid in which the patient was cured by blood transfusion. The typhoid symptoms began with an angina that lasted about three weeks. Fever then set in and within a week the patient's temperature had reached 40°C (104°F). The fever then abated. Three weeks later the temperature of the patient was normal and she thought she was cured. Suddenly, however, she began to bleed, first at the gums, and then through the skin, the kidneys and the conjunctivae. Her skin was covered with purpuric patches. The hemorrhages became more intense and the patient seemed to be bleeding to death. A transfusion of 300 cc of blood was given. The hemorrhage was completely checked within a few hours and the general condition of the patient was greatly improved. Four days later a second transfusion of 200 cc was given. After a few days the purpura was scarcely visible and the patient was soon able to leave the hospital. The authors consider this case significant because of the rarity of such a syndrome in which multiple, profuse and severe hemorrhages appear in the last stages of a case of typhoid. It is also especially noteworthy because of the apparently fatal prognosis and the striking therapeutic effects of the blood transfusions.

Effects of Ligature of Inferior Thyroid Artery on Calcemia and Functional Symptoms in Ankylosis.—Leriche and Jung report a case of multiple ankylosis of twelve years standing. The spinal column was completely rigid, only the slightest movements of rotation and flexion of the head were possible. The ankylosis had affected other articulations also for two years and the patient was almost unable to move at all and had intense pain. Since hypercalcemia was present the authors decided on parathyroidectomy. They removed a small body on each side, believing them to be the inferior parathyroids. One of the fragments, however, was merely a bit of fatty tissue. Immediately after the operation the patient showed a marked improvement: the pain disappeared and he was able to move his arms to turn himself in bed and finally to stand erect. The calcemia was reduced from 0.116 to about 0.09 Gm. Six weeks later, however, the ankylosis set in again and the patient gradually returned to his former condition although the calcemia remained normal. The authors feel that

the unfavorable developments in this case are not so discouraging as they appear at first because of the long duration of the disease. They consider it encouraging that any amelioration should have been produced. This case illustrates the extreme difficulty of identifying the parathyroids. The authors report a second case in which the ankylosis had begun five months earlier. Before attempting to identify and isolate the parathyroids they divided the inferior thyroid artery between two ligatures, one of them close to the branches of the artery extending to the superior and inferior parathyroids. Although the fragment that they removed, as in the first case, did not prove to be parathyroid, the ligatures served to decrease the glandular secretion and the patient's condition was immediately improved. The calcemia was lowered, the pain disappeared and wherever the ankylosis was not complete, mobility of the joints was restored. The amelioration has persisted for four months. The authors feel that this case demonstrates the efficacy of parathyroid operations performed sufficiently early in the development of the disease.

The Individual Factor in Reactions from Injections of Camphor.—By means of a number of experiments, Busquet and Vischniac show that the local reactions sometimes produced by subcutaneous injections of camphor are not the result of the olive oil in which the camphor is administered, nor of the accidental contamination of the material injected nor of the faulty technique nor of any properties of the camphor itself. The symptoms are evidently caused by an individual predisposition of certain patients. The authors proved experimentally that an abnormal circulatory condition in the area of absorption of the medicament favors the production of inflammatory reactions by the injection of camphor in either oily or aqueous solution.

Prophylaxis of Divers' Disease.—Blattner and Zangger point out that the waterworks that some cities in Switzerland have at deep lakes sometimes make it necessary for divers to work at a depth of about 40 meters. In rendering expert opinion on the death of a diver the authors stress that the diver had risen to the surface rapidly and that the extreme difference in pressure had caused the hemorrhages and death. In order to avoid such occurrences the divers should be given instructions, so that they will understand and adhere to the rules that are given for their safety. The authors think that in order to avoid similar fatalities as the one described a high pressure apparatus should be kept in readiness wherever divers have to work at depths of more than 12 meters so that if the diver is forced to come up rapidly the apparatus will be there to help in the adjustment of the pressure and thus prevent hemorrhages and death.

- Treatment of Tuberculous Cystitis. G. Pieri —p 454
- *Inguinal Hernia of Stomach. V. Novaro —p 483
- *Renal Changes Following Cauterization. R. Palma —p 509

Inguinal Hernia of Stomach.—Novaro describes in detail a case of mediogastric strangulated hernia and, in that connection, gives a survey of inguinal hernia of the stomach, reporting chronologically the nineteen cases described in the literature and studying the etiology, the pathogenesis, the pathologic anatomy, the symptomatology, the diagnosis, the course and the

prognosis and the treatment. He treats also the various complications: strangulation, stenosis, obstruction, adhesions, inflammation.

Renal Changes Following Cauterization—Palma studies, first, the changes that occur in the kidneys as a result of their cauterization, second, whether, as a result of circumscribed cauterizations, lesions develop in more distant parts, and, third, whether, as a result of the cauterization of one kidney, changes are brought about in the opposite kidney. From his researches it appears that cauterization of the kidneys constitutes a trauma not always compatible with the life of the animal, even though the intervention involves only one of the kidneys, the other being intact. Even superficial lesions damage the whole organ in its anatomic integrity. Aside from the immediate damage, the cauterizations are the cause of remote lesions, owing to the fact that a phase of connective tissue organization follows the initial lesions. The cystic dilatation of the renal tubules may be regarded as a direct consequence of the sclerosis of the connective tissue which causes circulatory disturbances through the lesions of the vessel walls and constriction of the renal tubules. As a result of the cauterization of one kidney, severe lesions of the opposite kidney develop, although they are transient. As to the explanation of these lesions, the author does not favor so much the idea that they are due to the action of a specific toxin, developing from the products of autolysis of the cauterized renal tissue, on the opposite kidney, but thinks rather that the changes are associated with a toxic action similar to that which any other toxic substance would excite if introduced into the organism and eliminated through the kidneys.

*Researches on Postoperative Hyperglycemia B Bonomini—p 1119
*Negative Experimental Observations on Tar Cancer U Fabris—p 1148

Researches on Postoperative Hyperglycemia—Bonomini, in summarizing the outcome of his research, states that the course of the curve of postoperative hyperglycemia appears in a certain relation with the behavior of physiologic factors that regulate the glycemia and also with organic changes due to diseases of a surgical nature. The influence of the emotions on the curve is, however, slight. The relation between hyperglycemia and postoperative acidosis is frank but not so intimate as some authors make it appear. Also a relation with postoperative hyperuremia is evident. No relation, however, was found between the hyperglycemia and the duration of the anesthesia and the acetoneuria. The operative hyperglycemia has been, in the author's cases, more or less intense but always of short duration. It reaches its culmination toward the end of the anesthesia and decreases steadily, disappearing usually after twenty-four hours. It is prevented by the intravenous injection of a sufficient quantity of insulin (from 10 to 15 units).

Negative Experimental Observations on Tar Cancer—Fabris, having never been able to produce tar cancer after numerous experiments on about 600 animals, holds that the prolonged irritating action of tar (coal tar, Norway tar) may prepare a terrain adapted to the development of blastomas in the sense of provoking an antitlastic dysfunctioning in the various tissues of the organism. For the final causation of the cancer some parasitic agent must become associated which constitutes for Roncali and his school the true specific element in the appearance of the blastoma.

- *Ether in Treatment of Traumatic Tetanus C Salvioh—p 848

Ether in Treatment of Traumatic Tetanus—Salvioh treated three patients with grave traumatic tetanus (in two of whom the evolution was known to be at seven and eight days respectively after the wound) by the rectal administration of a mixture of ether in oil as coadjuvant treatment with tetanus antitoxin. All the patients recovered. To verify the favorable action of the method on the evolution of the disease, animal experiments were made. In rabbits injected with fatal doses of tetanus toxin the rectal administration of ether did

not prevent death but prolonged the life of the animals longer than that of control animals. The repeated administrations of mixtures of a weak concentration of ether caused a condition of cachexia in the animals, probably the effect of the ether. The mechanism by which ether acts on the evolution of tetanic intoxication is unknown.

Subserous Fibromyoma of Uterus with Torsion of Pedicle A Dallera—p 359
Roentgen Physiology of Uterus and Tube A Dallera and A Rossi—p 373

Action of Methenamine on Uterine Contraction—Veicest is convinced that methenamine used intravenously offers in the obstetric clinic an effective means for the stimulation of uterine contractions or for the provocation, in suitable cases, of labor, without injury to the mother or to the fetus.

Changes Induced in Uterus by Irradiation of Uterine Tumors—Macchiarulo's histopathologic researches lead him to these conclusions. Irradiation in ordinary therapeutic doses affects the uterine mucosa, producing various degenerations of the cellular elements: pyknosis, karyorrhexis, vacuolation and changes in the aspect of the glands. Not even the muscular tunic of the uterus is immune to the action of the rays—atrophy, necrosis and fibrosis. The cell resistance of the uterine vessels is suppressed and these show various changes in the vascular tunics. From the researches of the author there develops evidently an angioplasmia in the irradiated tumors. The histochemical changes that are observed in fibromyomas extend to all neoplastic elements: muscular fibrocytes, connective tissue fibers, vessels. The author ascribes the changes to factors of a chemical, physical and colloidal nature called into action by the irradiation. The author agrees with previous investigators in attributing to a reaction of the mesenchyma the leukocytic lymphocytic plasmacellular and histocytic infiltration observed in irradiated tumors. The loss of the cilia, the rupture of the cell nucleus and vacuolation of the elements of the tube are phenomena specifically assignable to the modifying action of the intra uterine radiant energy. Emanations of radium coming from the uterine cavity produce atresia of the follicles in advanced maturation in the prolapsed ovaries and in a state subject to the influence of irradiation. It is possible, however, that the follicles, after a period of latency, reacquire their normal function.

*Vomiting of Tuberculous Patients Treated with Intravenous Injections of Hypertonic Solution of Sodium Chloride R F Vaccarezza C A Videla and G Pollitzer—p 747

Vomiting of Tuberculous Patients Treated with Intravenous Injections of Hypertonic Solution of Sodium Chloride—Vaccarezza et al used with success intravenous injections of 10 cc or a 10 per cent solution of sodium chloride in the treatment of vomiting of tuberculous patients. During the first two or three days two injections are given daily, and then one injection should be given daily during a period that varies according to the results obtained but which as a rule may be prolonged for about one week. The injections should be given long after meal time to avoid a reaction of the organism manifested by the appearance of nausea. Hypertonic solution of sodium chloride used when freshly prepared has a rapid and marked action in arresting the vomiting of tuberculous patients. As a rule the vomiting disappears after the first injection though sometimes three or four injections are necessary for its complete disappearance. Early discontinuance of the treatment may cause a reappearance of the vomiting in

which case the treatment should be repeated. The authors gave the treatment to eleven patients with pulmonary tuberculosis with several types of vomiting (emetic cough, simple vomiting merely to expel food, or maternal vomiting, with either mucus or bile). In ten of the patients, the vomiting disappeared. In the remaining patient the results of the treatment were fair (diminution of the amount vomited and in the frequency of vomiting, but not complete disappearance of it). In some of the patients the disappearance of the vomiting was associated with the improvement of some other symptoms, such as the diminution of the fever, increased appetite and feeling of well being. The authors consider the number of patients treated hitherto as being too small to permit one to draw conclusions.

Uronephrosis Treated by Denervation of Renal Pedicle and Nephropexy—Salleras says that the appearance of repeated attacks of renal colic suggests the occurrence of slight uronephrosis. Pyclography and pycloscopy are of value for the early diagnosis of the condition when the distention of the pelvis and tubules of the kidney with urine is still moderate, thus permitting the performance of an operation by which a reasonably good functioning kidney may be secured. As a conservative operation to return the kidney, the author advises the performance of denervation of the renal pedicle, followed by nephropexy. He obtained good results with the operation in four patients whose ages ranged between 25 and 33 years. The reports and pyclographic observations of these cases are given. The action that denervation of the renal pedicle has on the renal pain is due to the suppression of the periaarterial sympathetic fibers. The fixation of the kidney immediately after the performance of the denervation of the renal pedicle prevents the ptosis of the organ. In cases of abnormal implantation of the ureter in the pelvis, the fixation of the kidney as high as possible corrects the abnormality and provides a drainage of the kidney, which drainage is better than it was before the operation. When slight uronephrosis is caused by the presence of anomalous vessels of small caliber, the ligation of the vessels and liberation of the ureter should precede the denervation of the renal pedicle, which in turn precedes nephropexy.

Efficacy of Commercial Preparations of Anterior Lobe of Hypophysis—Guitarte's article is a preliminary report on the results of his experiments to prove the efficacy of commercial preparations of the anterior lobe of the hypophysis. The author has found hormones of the anterior lobe in the preparations by the administration of which to young rats he has obtained positive and sometimes intense reactions. Freshly prepared extracts from the anterior lobe of the hypophysis should be used because they are subject to a rapid deterioration. The author makes reference to the conflicting opinions in the literature with regard to the merit of pituitary preparations. He states that pituitary preparations, when freshly prepared, prove to have a marked therapeutic action when administered orally, intramuscularly or intravenously to human beings.

Nondiabetic Infantile Glycosuria—Landabure reports the case of a patient, aged 5 years, who since the age of 5 months had had permanent glycosuria that was not modified by the diet or by insulin therapy. The patient had crises of vomiting with acetoneuria at intervals of about three months, which disappeared spontaneously. He developed normally, however, with no symptoms that would indicate a diabetic origin of his glyco-

suria. The author says that, in cases of infantile diabetes, acidosis appears unexpectedly even if constant attention is given to the patients, while in his patient the presence of glycosuria was well tolerated, though the patient never received special care for diabetes because he was not a diabetic patient. His glycosuria was associated with a normal glycemia. There were no disturbances of the gluside metabolism (the test for the diagnosis of hyperglycemia was negative). There was also a diminution of the renal threshold. The clinical and the biologic diagnosis was that of nondiabetic glycosuria or renal diabetes. The author considers the child's condition rare because of the fact that, whereas he has observed more than 2,000 cases of diabetic glycosuria, he has found only 6 cases of nondiabetic glycosuria and while he has observed a total number of 30 glycosuria patients, all of whom were diabetic, the patient spoken of was the first who had a renal glycosuria of nondiabetic origin.

Excision of Presacral Nerve in Dysmenorrhea and in Pelvic Neuralgia—Vila and Viriot say that with the proper selection of cases resection of the presacral nerve is indicated because of its gratifying results in all cases of intractable dysmenorrhea and pelvic neuralgia in which medical treatment fails. The authors resorted to this method in seventeen patients, aged from 17 to 39 years. Disturbances of the bladder or of the rectum were not observed. There were two or three spontaneous micturitions, as well as free elimination of gas since the first day after the operation. Menstruation appeared in all cases two or three days after the operation, regardless of the date of the previous menses. Resection of the presacral nerve (superior hypogastric) was the only operation performed in six cases of essential dysmenorrhea not associated with an organic or genital lesion. There were five recoveries and one failure. The resection of the presacral nerve was associated with an adnexopexy in six cases of sclerotic ovaritis and with some other operations on the genitalia in five cases in which lesions of the genitalia complicated dysmenorrhea. Of the entire group ten patients (58.82 per cent) were cured with complete disappearance of both dysmenorrhea and pelvic pain, three patients (17.65 per cent) showed a marked improvement, while in four patients (23.53 per cent) the treatment failed.

Tuberculosis Prophylaxis with BCG Vaccine—Nohlen describes experiments in which he noted that in monkeys treatment with BCG vaccine did not prevent a subsequent natural infection with virulent tubercle bacilli. The percentage of infections, however, was much higher in animals kept indoors than it was in animals kept in the open air.

Course of Tuberculosis Through Generations—Andvord states that the tuberculosis mortality shows a characteristic highly regular wave movement that during several decades has been on the descent over practically the entire civilized world. In England the decrease in the tuberculosis mortality began in the middle of the nineteenth century whereas in Nor-

way it did not begin until 1885. The decrease progressed from generation to generation since the members of each new generation period seem to have a greater resistance with regard to the tuberculosis toxin than did the members of the preceding period. Each generation has its own definite curve since the degree of infection during the first years of childhood acts as an index for the mortality percentage for the subsequent age periods, a decrease in the tuberculosis mortality during the first years of childhood is followed by a similar decrease from twenty to twenty-five years later in adults.

Spleen Extract in Treatment of Pulmonary Tuberculosis—Matrusch has used spleen extract with success over a period of one and one-half years in the treatment of 140 persons with pulmonary tuberculosis. Roentgenograms of several patients taken before and after the treatment show definite indurative transformation processes. The stabilization of the defense powers of the patients following the ingestion of spleen extract is shown by the disappearance of the deviation to the left and the appearance of lymphocytes and eosinophils in the leukocyte picture.

Metal Salt Treatment of Tuberculosis—Gessner and Siebert report their observations in several large series of experiments on the modification of experimental tuberculosis in guinea-pigs by the parenteral administration of metal salts (manganese chloride and beryllium chloride combined and manganese chloride alone). Although the treatment with metal salts at first showed a transient favorable action on the tuberculosis, larger doses accelerated the course of the disease. It is stated that the results of the experiments are considered not as a refutation of the value of metal salt therapy in experimental tuberculosis in animals but as evidence that in this form of therapy the most important factor is the correct dosage.

Resection of Scalene Muscles as Supplementary Operation in Avulsion of Phrenic Nerve—Kochs et al first describe experiments that they performed on monkeys to study the effects of resection of the scalene muscles. After having demonstrated that the operation was completely harmless they performed it as a supplementary operation to avulsion of the phrenic nerve in twelve persons with unilateral pulmonary tuberculosis. In some of the patients the transverse phrenicotomy incision was used but it was found to be unsatisfactory because it did not give good exposure of the median and posterior scalene muscles. Therefore Sauerbruch's oblique phrenicotomy incision extending from the middle of the posterior edge of the sternocleidomastoid muscle down to the clavicle was adopted. After the phrenic nerve has been exposed and avulsed the anterior scalene muscle is dissected free in order to separate it posteriorly from the nerve plexus and medially from the large blood vessels. The muscle is then divided a short distance above its lower attachment. The retracted stump of the muscle is grasped with forceps and drawn forward, a piece 2 cm long is then resected. Simple division of the muscle gives unsatisfactory results because it is followed by an early connective tissue union of the two ends. The lateral edge of the brachial plexus is then exposed and is carefully drawn anteriorly and medially with a blunt retractor. This exposes the wider median scalene muscle, which is also divided in this step of the operation care must be taken not to divide even the finest nerve fibers that pass over or through the muscle. Particularly in the division of the posterior part is great care necessary in order not to include a part of the plexus in the scissors. Usually the short stump retracts so far posteriorly that there is only a slight possibility of performing resection. The posterior scalene is usually adherent to the median scalene and frequently cannot be separated from it except in cases in which a previous avulsion of the phrenic nerve or pneumothorax treatment has been followed by secondary hypertrophy of the muscle. After all three muscles have been divided or resected there is present a cavity somewhat larger than a pigeon's egg, which is traversed by the plexus. With a careful technique the hemorrhage is minimal and primary closure of the wound can always be performed. Only about fifteen minutes is required for the entire operation and the after treatment presents no difficulties or complications. Just as in all operations that result in a compression of the tuberculosis lung there occurs a moderate increase in tempera-

ture, which, however, lasts only two or three days. The amount of sputum, which is sometimes increased slightly during the first two days following the operation, diminishes rapidly and markedly. In all twelve patients in whom this combined treatment was used the permanent results were excellent and unquestionably better than those obtained with simple avulsions of the phrenic nerve. Moreover, in none of the cases did the authors note defects or disturbances attributable to resection of the scalene muscles. They recommend a trial of this harmless and in some cases markedly beneficial combination of avulsion of the phrenic nerve and resection of the scalene muscles.

Deutsche medizinische Wochenschrift, Berlin

56 1937 2030 (Nov. 21) 1930 Partial Index

- *Treatment of Puerperal Peritonitis H Runge—p 1989
- *Fatal Poisoning Caused by Mushrooms (*Helvella Esculenta*) H Stahr—p 1993
- *Diagnosis of Pulmonary Tuberculosis by Demonstration of Bacilli H Opitz—p 1995
- Agranulocytosis W Nipperdey—p 1997
- Relation Between Diabetes and Trauma W H Veil—p 1999

Treatment of Puerperal Peritonitis—Runge points out that, while formerly many leading authorities advised against surgical treatment in puerperal peritonitis, recently many have recommended it. In consideration of the fact that without operative treatment the mortality rate is almost 100 per cent and that early operation saves many lives, this attitude seems justified. The author discusses the various causes of puerperal peritonitis, and he directs special attention to that form which results when substances with toxic action are introduced into the uterus in order to effect an abortion. He gives the clinical histories of three patients in whom puerperal peritonitis was caused by the injection of soap suds into the uterus. One of these patients, who was operated on twelve hours after the injection, recovered, whereas the other two who came under clinical observation only on the third and the fifth day, respectively, died. From this the author concludes that symptoms of peritonitis after soap suds injections necessitate immediate operative intervention. However, in deciding on the necessity for surgical treatment in puerperal peritonitis one does not have to consider the etiology. The fact that a puerperal peritonitis exists indicates that surgical treatment is necessary. A tabular report shows the great significance of an early operation. Of twelve patients who received surgical treatment during the first twenty-four hours after the manifestation of the symptoms of peritonitis, nine recovered. Of five patients who were operated on during the second twenty-four hours only one recovered and those who received operative treatment later than that all died. In evaluating the various surgical methods the author comes to the conclusion that the supravaginal removal of the uterus and of the ovaries but with conservation of a stump of the portio vaginalis, is the best method. During the after-treatment the circulation and the peristalsis should receive special consideration. Advisable is an intravenous continuous drop infusion of a 5 per cent solution of an invert sugar. In all patients who received surgical treatment and who recovered abscesses developed, which in some instances had a phlegmonous character but which did not greatly retard the healing process. In the conclusion the author stresses that septic abortions should always receive clinical observation because only thus is the early recognition of peritonitis guaranteed, and the opportune time for an operation is not neglected.

Fatal Poisoning Caused by Mushrooms—Stahr reports two cases of poisoning with fatal outcome, resulting from ingestion of mushrooms of the variety of *Gyromitra esculenta* or of *Helvella esculenta*. In both instances the necropsy showed that death was caused by helvella acid poisoning. The author does not accept the hypothesis that the toxicity of *Gyromitra esculenta*, the so called turban-top, varies that in certain localities and at certain times, they are more poisonous than usual. He thinks that they are always poisonous until they are cooked at least five minutes and the cooking water is poured away. The cooking does not destroy the toxic substances but they pass into the water, and this therefore should always be completely removed. The fatal outcome of the cases reported may be due to several factors. It is probable that the mushrooms had not been boiled for a sufficient length of time or that the water had not been completely removed. However the large

quantities of the mushrooms ingested, and constitutional anomalies of the patients, in one case a diseased liver, and in the other case a gastric ulcer, may have aggravated the condition.

New Investigations on Diagnosis of Tuberculosis by Demonstration of Bacilli—Opitz states that although epithelioid and perifocal infiltrations in children are generally thought to be closed forms of pulmonary tuberculosis, tests revealed that the majority of such children excrete bacilli. Among thirty of these patients, between 4 months and 4½ years of age, there were only two in whom the tests gave negative results. To the question as to when an originally open tuberculosis can be considered cured or, at least, closed, the author replies that this can be determined only by the animal experiment, because the examination of the sputum occasionally gives negative results when the animal experiment reveals the presence of bacilli. In discussing the care of such patients who have a closed tuberculosis but who, nevertheless, disseminate bacilli, the author states that they should be cared for in special stations, because they represent a danger for healthy children, but at the same time it would not be right to put them in the same wards with patients who have an open tuberculosis.

Copper Therapy of Anemia in Infants—Schiff et al. reasoned that because Steenbock had obtained favorable results with copper therapy in rats that had been made anemic by feeding them only with cow's milk, copper might likewise be helpful in anemia in infants. Accordingly they instituted copper therapy in four anemic infants. In two of them the anemia accompanied erythrodermia, in one it concurred with pylorospasm and in the fourth with severe visceral syphilis. The nurslings were given twice daily 20 drops of a 1 per cent solution of hydrous copper sulphate, which is equal to about 5 mg. of copper per day. Under the influence of this therapy the blood picture improved steadily in all four cases. The authors conclude that, although the number of cases in which copper therapy proved helpful is still limited, copper has a distinct therapeutic value. They recommend this treatment for further investigation, and they themselves are making observations on anemic premature infants and are conducting experiments.

Treatment of Pernicious Anemia with Preparation from Gastric Mucous Membrane—Henning and Steiger reasoned that if in the normal gastric juice there is a substance which stimulates the formation of blood it must be produced in the gastric mucous membrane. Accordingly they treated patients who had pernicious anemia with a preparation from the gastric mucous membrane of hog stomachs. The preparation was employed in five cases. The patients received daily from 40 to 80 Gm., a quantity equal to the mucosa of one or two stomachs. When given with broth or with applesauce the patients found this form of treatment entirely agreeable. The effect on the blood picture was favorable, the hemoglobin content and the number of erythrocytes increased steadily. Hydrochloric acid alcohol extracts of the mucosa were ineffective. The antineuritic substance was found in the fundus portion as well as in the antrum portion of the mucous membrane. Peptic ferment was detected only in minor quantities in the preparation from the mucosa of the corpus ventriculi and it was entirely missing in the preparation from the mucosa of the antrum. From this it may be concluded that the effect of the stomach preparation is independent of the peptic protein digestion.

Gout in Infant, Aged Five Weeks—Mayer von Schöpfung reports the clinical history of an infant with gout. Subcutaneous tophi were observed by the mother in the third week of life. The infant, who was breast-fed, had vomited since birth after nearly every meal. Because of the constant vomiting a physician was consulted, who thought of pylorospasm and sent the infant to the clinic. There were no signs of pylorospasm. The diagnosis was not clear at first. Considered were multiple abscesses, congenital neoplasm with metastases or tendovaginitis fibrinosa. Treatment was of little avail and the child's condition grew steadily worse. The puncture of a pea-sized tumor on the right ankle joint yielded a snow-white, pasty substance. Following the microscopic examination of this substance, gout was thought of. The tophus growths progressed rapidly and the child died. The author points out that the significance of this case for the gout problem lies in the fact that only endogenous purines formed the uric acid. The predominance of the constitutional pathologic factor is marked. Exogenous influences such as foods, environment and mode of life had no influence on the development of gout in this case. The question as to what causes the retention of uric acid has not become clear. Microscopic examination of the bones revealed neither primary nor secondary inflammatory changes. The kidneys had the characteristics of the gouty contracted kidney. Crystal deposits were present in unusually large amounts and they were predominantly in the interstitial tissues. Tissue necroses were not observed.

Crusade Against Malaria in Italy—In the first part of the article, Schilling discusses the development of malaria parasites. In discussing the various methods of combating malaria that are employed in Italy, he first mentions quinine therapy. The state distributes quinine among the patients at a low cost. However, the author thinks that supervision is necessary because without supervision many patients discontinue the use of quinine as soon as the fever disappears, and such a therapy is of course incomplete. The mechanical protection, namely, the screening of the houses, is enforced by the Italian railroads. The drainage of marshy districts has also been a great help in combating malaria, and, in order to destroy the mosquito larvae in the canals, gambusias have been introduced into the canals. In shallow waters such as the 'Lago di Trignano' the breeding of mosquitoes is prevented by counteracting the vegetation and by scattering paris green around the edges. The result of all these measures has been that in the malaria areas the mortality rate from malaria has considerably decreased.

Role of Liver in Regulation of Tonus of Sympathetic Nervous System—Danielopolu et al. state that in a former article they had shown that the liver has the power to retain choline injected into the portal vein or into one of its branches. In this report they describe their further experiments on dogs. First they determined the smallest doses of choline and epinephrine that will produce a circulatory effect when the injection

is given into a peripheral vein, and then the smallest doses that will produce a circulatory effect when the injection is given into the portal vein or into an intestinal vein. Further they studied the action of epinephrine and choline when they were injected into the hepatic artery, into the renal artery or into a peripheral artery. These comparative experiments were made in order to determine whether the action was due to a certain tissue or whether it was a specific action. Finally they injected choline and epinephrine into a peripheral vein, into an intestinal vein and into the portal vein of dogs, which, on the two preceding days, had been given injections with tolylenediamine. The epinephrine and choline injections were given forty eight hours after the first tolylenediamine injection. At this time the dogs already showed icterus and the liver cells showed considerable changes. The authors' observations are summed up as follows: 1. Epinephrine and choline injected into the portal or hepatic veins has a circulatory effect only when the doses are much larger than those which are effective in a peripheral vein. 2. The liver exerts a regulatory influence in that it maintains a fixed humoral medium of substances which influence the sympathetic system. 3. The liver, which has become insufficient as the result of injections of tolylenediamine, loses the capacity for retention of choline and epinephrine. 4. The changes in the sympathetic tonus, which are also noted in the sinus bradycardia during icterus are caused by the insufficiency of the liver that accompanies icterus or, more precisely stated, they are due to a deficiency in the regulatory action of the liver on the tonus of the sympathetic nervous system.

Clinical Determination of Intracranial Trauma in the New-Born—On the basis of the fact that every extravasation in the body causes changes in the serum, Preissecker attempted to detect intracranial traumas by examining the pigment content of the serum. He points out that in the colorimetric investigations consideration should be given to the physiologic hyperbilirubinemia that exists in the new born and that causes a heightened yellow discoloration. In infants with intracranial hemorrhages, however, the serum contains besides this yellow bilirubin pigment, a yellowish brown pigment from a hemoglobin derivative. The author determined the pigmentation of the serum in a number of new born infants in whom intracranial hemorrhage was suspected and also in normal new-born infants. In summing up the results of his tests he says that in a new-born infant with suspected cranial trauma an intracranial hemorrhage may be assumed when the serum shows a decided yellowish brown discoloration, provided, of course, there are no other extravasates such as a cephalematoma. The yellowish-brown pigment from the hemoglobin derivative appears in the serum on the second day; it is most pronounced on the third day, and after that it gradually disappears. In icterus neonatorum there also exists an increase in the bilirubin pigment. However, in this condition the serum has a pure yellow color, and thus it can be differentiated from the yellowish brown pigmentation in case of intracranial hemorrhage.

Treatment of Trigeminal Neuralgia—Lux first criticizes the generally accepted theory of the etiology of trigeminal neuralgia and the methods of treatment, which had been based on this theory. In observing patients during attacks of trigeminal neuralgia he noted a hyperemia of the skin in the region of the trigeminus and an increased perspiration and tear secretion. The patients tried to counteract their pain by pressing and massaging the painful region. It was also observed that in the intervals between the attacks there was neither hyperalgesia of the skin nor pressure pains. From this the author concluded that the phenomenon is due to vascular spasms in the region of the ganglion. He hoped to overcome these spastic conditions by diathermy treatment. Experiments on cadavers convinced him that by applying electrodes to both eyes and to the back of the neck, the entire ganglion and its surroundings could be influenced. When the method was employed on patients it was found that their eyes were extremely sensitive to pressure. But this difficulty was overcome by padding them with cotton that had been saturated with physiologic solution of sodium chloride and by using electrodes of wire netting. The treatment was first employed on two patients during an attack and the results were favorable. During the following five years the author

employed this therapy on about 100 patients. He gives several case reports. The number of treatments necessary differs in each case. In some instances from five to ten treatments were sufficient; in others, as many as between twenty and forty were needed. The author recommends the further investigation of this treatment.

Tuberculous Nephritis. Clinical Aspect—On the basis of six cases that they observed in children with tuberculous arthritis, Simon et al. discuss the clinical aspect of tuberculous nephritis. The general condition of the patients remained unchanged in those in whom the arthritis was healing, the state of nutrition and the weight and temperature curves were the same as in joint tuberculosis without involvement of the kidneys. In one of the six children there occurred occasionally attacks of pain in the kidney region, which lasted several days. These attacks of pain which necessitated the administration of a narcotic, appeared one and a half years after the first symptoms and were not accompanied by other symptoms, with the exception of an occasional increase in the number of leukocytes, the urine remained unchanged during the attacks of pain. In most of the children the blood pressure was slightly or definitely above normal. In none of the children was the heart enlarged. The speed of erythrocyte sedimentation was the same as that noted in tuberculous arthritis. In all the children the bladder capacity was normal. Cystoscopic examination did not reveal changes in the mucous membrane that could have been considered typical for tuberculosis. The region of the ureters was normal in all the patients but in three of them there was a redness of the neck of the bladder or of the trigon.

Nephrolithiasis with Three Thousand Stones—Sacharoff reports a case of nephrolithiasis in a man aged 33, who had never had attacks of severe pain or disturbances of urination but in whom roentgen examination disclosed a large number of stones in the left kidney. Because of a feeling of heaviness and pain in the region of the kidney it was removed. When the specimen was sectioned it was found that the kidney pelvis was greatly dilated and that the kidney consisted of several cavities that contained a large number of stones of various sizes. The thin walled cystlike projections proved to be the hydronephrotically dilated calyces. The renal parenchyma was preserved in only the upper pole, in the middle part of the kidney and in the lower pole the parenchyma had disappeared completely. In the mucosa of the pelvis and of the dilated calyces there were no signs of inflammation. The total number of stones removed was 3,000 and their weight was 21.5 Gm. All the stones consisted of calcium phosphate. The absence of colic in the uricemia was explained by the fact that a large pelvic stone had blocked the ureteral orifice almost completely and had prevented the passage of small stones through the ureter.

Complications Caused by Salpingography—Hoffmann gives the history of salpingography and then reviews the literature. He points out that several authors report complications caused by the contrast medium. Then he gives a detailed description of a case in which granulomas remained after salpingography had been done. It was found that the contrast

medium had been retained by the left tube. After mentioning other complications that have been observed after salpingography, the author comes to the conclusion that, especially in cases of sterility, salpingography should not be done. It may cause new infections, a flaring up of old processes or an occlusion of the tubes, or the contrast medium may be retained. It is stressed that insufflation of the uterine tubes does not involve such dangers as salpingography, and that in cases of sterility it gives the same or even better results than salpingography.

- *Encephalitis Following Serious Burns in Child Aged Two Years L. Coenen—p 235

Bronchostenosis in Children Resulting from Swollen Hilus Lymph Nodes—Huizinga describes in children six cases of bronchostenosis resulting from a swelling of the hilus lymph nodes. In all six patients the manifestations began in an acute manner and the patients were sent to the clinic under the suspicion of the presence of a foreign body. The correct diagnosis can often be reached only by bronchoscopy. In two cases an acute lymphadenitis was involved, and in three or four cases tuberculosis was certain. In case of rupture good therapeutic results can often be secured through bronchoscopy, either by the removal of granulations (two cases) or by the elimination of a caseous mass in the more acute stage (two cases). The most common place for the rupture is the point where the trachea merges with the right bronchus.

Encephalitis Following Serious Burns in Child, Aged Two Years—Coenen reports the case of a child, aged less than 3 years, who was seriously burned over his whole body by tipping boiling water over himself. The following day a temperature of 40.5 C (104.9 F) developed, also convulsions. The child (a twin and born prematurely at seven months) lapsed into a comatose state, the eyes became fixed toward the left and Kernig symptoms and stiff neck developed. The burns healed slowly but manifestations pointing to changed conditions in the cortex cerebri and the meninges appeared. The child had had a bad fall three months previously. Encephalitis following burns has rarely been reported in the literature. The earlier cases are cited. How is the encephalitis to be explained? It might be assumed that there was a latent encephalitis and that it was brought out by the burns, but such an assumption would be justified only if several other cases of encephalitis had been reported at that time, but such was not the case, hence, it must doubtless be assumed that the encephalitis developed as a result of the burns. Toxic substances may have formed that induced the encephalitis. The child has not yet recovered sufficiently to recognize his father.

Ova of *Trichosomoides* as Nuclei of Experimental Stones of Bladder—Van Leersum reports that, in connection with a biologic vitamin A determination in a sample of cod liver oil with phosphorus, some peculiar gritty crystals were found in the bladder of one of the rats. The substance was a calcium salt—in all probability calcium phosphate, of which the concretions commonly consist that one finds so often in the bladder and in the kidneys of rats that are deficient in vitamin A. Some of these crystalline bodies had a nucleus of a brownish color. The colorless crystals, as was to be expected of calcium phos-

phate, dissolved in acetic acid, but the brown nucleus was resistant. On closer examination, certain peculiarities were discovered that led to the assumption that formed elements were involved, probably the ova of a parasite. A more extensive inquiry was instituted, and in seven of the nineteen rats that had served for the test threadlike micro organisms were found in the bladder. Microscopic inspection revealed a large number of eggs that in color and form resembled the objects in the crystalline concretions. Professor Ihle, to whom the preparations were referred, concluded that the organisms belonged to the genus *Trichosomoides* and were likely specimens of *Trichosomoides crassicauda* Railliet. The presence of the eggs in the concretions was doubtless a chance occurrence.

- *Relation of Leukocytes After Intramuscular Injection of Sulphur S. A. Holbøll and G. Herborg—p 1027
- *Case of Pancreatogenic Steatorrhea J. F. Holst—p 1032

Relation of Leukocytes After Intramuscular Injection of Sulphur—Holbøll and Herborg state that after an intramuscular injection of sulphur there was a considerable increase in the number of leukocytes in the blood, the value frequently rising to more than 20,000, in one case, to 31,000. The rise was in the main parallel to the fever reaction and due exclusively to an increase in the number of polymorphonuclear leukocytes.

Case of Pancreatogenic Steatorrhea—In Holst's patient typical symptoms of diabetes had set in more than ten years previously with the addition several years later of steatorrhea. He says that steatorrheas of various kinds may cause a picture strongly resembling pluriglandular insufficiency. Thrombopenia and polyneuritis, noted in his case and previously described in pancreatogenic steatorrhea, may also occur in steatorrheas of other kinds.

DIAGNOSIS AND MANAGEMENT OF THE ALLERGIC CHILD*

BRET RATNER, M.D.
NEW YORK

My purpose in this paper is to present a method of studying and directing the management of the allergic child from the standpoint of protein hypersensitiveness. Observations in both the experimental and clinical phases of this field have led to certain modifications in practice that may be of interest. I shall not quote extensively from the literature, for that would be foreign to the purpose of this paper.

At the outset, it is necessary to define the term "allergy" as it will be used here. This term was first utilized by Pirquet and Schick to designate an altered reaction of the body to a foreign substance whether purely protein or bacterial in nature. Its meaning in late years has become so broad as to include a large variety of altered reactions, such as those incident to tuberculosis, scarlet fever, rheumatism and other diseases. In the present studies its meaning is limited to specific hypersensitiveness clinically manifested as bronchial asthma, hay-fever, infantile eczema, urticaria and certain gastrointestinal disturbances. Explanations for the allergic state have been sought on other grounds because results have not been entirely satisfactory. I believe that the years will prove, however, that these failures were due to the lack of information in regard to the proteins and their ability to bring about a reaction under certain circumstances, rather than to an error in the original premise that specific protein hypersensitiveness is the cause of allergic conditions.

When a patient is presented for study the first step is to determine in a general manner whether or not the problem to be dealt with is an allergic one. If a history is given of recurrent bronchitis or pneumonia with low pyrexia, or if the child sneezes every morning on awakening or coughs a great deal at night and these conditions are paroxysmal there is a suggestion of respiratory allergy. If a child develops sneezing or coryza in the spring or in August there is a suggestion of hay-fever. If a history can be obtained of infantile eczema or recurrent attacks of urticaria an allergic origin is suggested. Even definite eczemas are not necessarily allergic if they are limited for example to a particular area and never spread to any other part. With a certain amount of experience after obtaining such a general history one can determine with a fair amount of accuracy whether a child is allergic. These general aspects are important for otherwise many cases

might be studied for protein hypersensitiveness only to be rewarded with negative results.

Historical data are of great importance, in some cases, indeed, the treatment is largely dependent on information that can be gleaned from the history. As I shall have occasion to reiterate many times, knowledge in this field is comparatively limited, and the process must of necessity be empiric. To be of any assistance, then the history must be most comprehensive. I shall consider it from various angles.

FACTORS IN DIAGNOSIS

Family History—Material gathered from family histories is not strictly of importance in the individual case but has been utilized in the discussion of the still moot question as to whether allergy is an hereditary disease or whether there exists in certain individuals a predisposition to the acquisition of protein hypersensitiveness which may be compared with the present attitude toward tuberculosis.

Therefore, if one is interested in this phase, there are just a few precautions to note. It is difficult to gather precise information when taking a family history. The physician's mind should be unbiased and he should exercise care not to force information that will suit his own views, for it is a simple matter to shape questions that will draw equivocal answers.

Specific History of the Child—All the factors attendant on the onset of the disease should be inquired into carefully for example the inquiry should be directed as to the places the patient visits the first ingestion of certain foods, the introduction of new bedding, or contact with certain animal pets, which all present suggestive data. With asthma the occurrence of attacks at night may indicate a relation to the bedroom, occurrence in the daytime shortly after a meal may indicate a relation to foods or it may be a combination of food and some external cause. It is also helpful to get an exact description of the most recent attack and all of the surrounding circumstances.

With eczema and urticaria a general idea of the occurrence of the attacks must also be obtained whether they occur at night or during the day is important for it is known that although eczema and urticaria as a rule are due to the ingestion of foods nevertheless an individual might have eczema or hives from external causes—as opposed to foods ingested. A striking case is that of a child who suffered from frequent attacks of angioneurotic edema and papular urticaria yet was found negative to all available protein tests but gave definite reactions to extracts of his pillows and mattress. Further inquiry revealed that his attacks of edema occurred before breakfast and his itching was most pronounced at night. Removal of his pillows and mattress resulted in a complete cessation of the symptoms. One year has elapsed since this observation.

* This work is being carried on under the Crane Fund for the Study of Allergic Diseases in Children.
From the Departments of Pediatrics and Immunology, University and Bellevue Hospital Medical College, New York University and Sydenham Hospital.

Relation of Antepartum Period to Sensitization—It has been demonstrated¹ that it is possible to sensitize actively a guinea-pig fetus in utero. With this factual evidence in hand I² later showed that there is a causal relationship in the human subject between the antepartum diet and the sensitization of a human fetus in utero. This has been traced to the excessive indulgence in particular proteins as a result of peculiar cravings which certain pregnant women have. This hypothesis may be offered as a possible explanation for the instances of children who, taking a certain food for the first time, develop an immediate anaphylactic reaction in the form of urticaria, eczema or other manifestations. Hence it is of importance to inquire carefully to the antepartum diet, for here one may find the cause of the allergic state in certain children which may easily correct in early case of eczema or hives. Such evidence must, of course, be corroborated by skin tests. In testing such cases one sometimes discovers potential sensitizations which have been established before birth, to foods with which the child has not yet come in contact. I do not mean to indicate that such an indulgence causes an allergic condition in each instance, for even in guinea-pigs it is impossible to bring about sensitization in each animal. What fundamentally predisposes an individual to the acquisition of sensitization—whether a human being or an animal—has not yet been discovered. I have not at any time suggested that this is the sole manner in which sensitization is acquired. I do suggest, however, that this is one possible way in which a fetus having such a susceptibility may acquire its original sensitization evidenced after birth on first contact.

Environment—Environmental conditions may also be causative factors in establishing a hypersensitive condition. It has been shown experimentally³ that guinea-pigs may be sensitized by the direct inhalation of antigenic dusts. As has been described in the paper of Figley and Elrod,⁴ castor bean dust, emitted by a castor oil factory, was the direct cause of a large number of cases of asthma in that district. Proximity to stables, chicken farms and other such dusty environments might also be the cause of allergic conditions.

The occupation of the parents may occasionally reveal the cause of the allergy in the child. This was demonstrated in a study on rabbit hair asthma.⁵ No rabbit hair could be found in the home of a child sensitive to this substance. The only possible clue was that the father worked in a felt hat factory. On further investigation, it was found that felt is manufactured from rabbit hair. In the process of his work, particles gathered on his clothing and person. The relationship was specifically proved when the child reacted positively to a skin test done with dust taken from the cuff of the father's trousers.

Another instance in which the parent's occupation was the offending cause was that of a butcher whose child was sensitive to various meats. The eczema of

the face was traced to the father's kisses. The father had a large moustache which he was in the habit of stroking when his hands were soiled from the handling of meats. After this situation was discovered and the father was instructed to clean his moustache and hands thoroughly before returning home, the child's eczema disappeared.

The home should be investigated for the detection and analysis of all dust-producing articles. It is curious how little people can or will tell about their homes, particularly with reference to objects that are likely to cause trouble. Bed clothes, furniture, floor coverings, decorations of all kinds, toys, personal clothing, pets, rodents, insects and insecticides have all been found to be causative agents in producing this condition.

In other words, since this is a branch of medicine which is still far from perfected, it is necessary to seek as much aid as possible from the history of the patient. After this has been ascertained, it is time to proceed with the skin tests.

THE SKIN TEST

The whole question of the proteins that are used in the skin test is one that requires much inquiry, proteins have not been standardized and it is possible that one is dealing with inactive proteins, on the other hand, reactions are obtained that are occasionally proved nonspecific, the number of proteins is still limited, although the number available has increased remarkably. Furthermore, in my experience, I have found patients who have not reacted to stock proteins—feathers for instance—but who do react to an extract from feathers out of their own pillows. Another most interesting example of this was recited to me by a dealer in ostrich feathers who reacted to feathers from one locality but not of another. These are all factors of which one must be cognizant, and which will make people less hasty to condemn the lack of success in individual cases studied in this manner. Therefore I reiterate that unless there are available protein extracts of all substances with which an individual is likely to come in contact, in the form of comestibles or environmental factors it is necessary to seek aid from the history in addition to what can be learned from the actual skin tests.

There are two major methods of doing the skin test, the scratch method and the intradermal method. The latter method is the intradermal injection of a protein solution. The scratch test is performed by applying to a scratch in the skin a drop of tenth normal sodium hydroxide in which is dissolved a minute amount of dry protein.

In favor of the intradermal method, the argument has been advanced that it is more sensitive than the scratch method, especially in cases in which the skin is not readily reactive. However, this argument may be used as well in its disfavor, because certain skins may react too readily, in which event the interpretations are difficult to make and therefore require wide experience and exceptional judgment. Furthermore, there have been reported violent reactions and even deaths from the use of the intradermal injections in patients that are exquisitely sensitive. The method is painful, time-consuming and difficult to perform on a resistant child. Since its results do not offer a greater degree of reliability, it seems to present a greater number of disadvantages than advantages.

The scratch method is simpler to perform and is not painful. A slight scratch—several millimeters—is made

on the skin with a Hagedorn needle. Greatest precaution must be taken to prevent trauma, since the drawing of blood tends to prevent the dissolved protein from entering the lymphatics. If the solvent dries before the protein is completely dissolved, additional sodium hydroxide is applied and care must be taken not to traumatize or irritate the skin at the point where the protein is being dissolved. The protein may be applied and dissolved readily by means of a flat toothpick. It may seem needless to call attention to the fact that test material must be carefully labeled—both bottles and stoppers—to obviate any interchange, and that a fresh applicator must be used for each test.

It is essential in doing the scratch test to have the numerical scratches so arranged that it is impossible to read falsely any given test. In order to accomplish this, as a rule, the number of scratches done at a given time is always continued in the same order, that is, if five tests are done horizontally, a series of five is carried throughout the ensuing tests.

The accurate numbering and labeling of each test therefore is of utmost importance.

Skin Reaction—The skin reaction varies in intensity in different individuals. If a particular skin is highly reactive, a small wheal will be of little consequence and a positive reaction must necessarily be a typical wheal with definite pseudopods.

In a skin that is nonreactive, just as much care must be taken in the interpretation of the skin reaction, for here even a small wheal of a few millimeters may definitely be regarded as positive. Persistent erythema is often to be regarded as positive.⁶ However, in such instances the test must be most carefully controlled and only after repeated corroboration may it be regarded as positive.

Locality of the Skin Test—Certain areas of the body have been designated as most reactive—the bend of the elbow, for example—and it has therefore been advised that the tests be performed at that point.

In the early days of my work, I noted that the particular area of the body on which the skin test is performed does definitely affect the reaction. If the same protein is tested in as many as thirty different parts of the body there will be all gradations of reactions elicited, from a negative to a definitely positive one. Even so slight a distance as 2 cm from one scratch to another might give different reactions. My results, therefore, have led to the conclusion that individuals differ markedly, and there is no particular part of the body that is specifically more sensitive in all individuals.

Recently Alexander,⁷ working with the intracutaneous method, reported that he similarly has found such a marked variability of sensitive skin areas and that a test might be negative in one area and positive in another. This irregularity of the skin receptivity therefore holds for the intracutaneous and scratch methods.

Suggestive reactions should be repeated in various parts of the body and a responsive area may be found on which more positive results can be obtained.

The Skin-Negative Type—There are undoubtedly many patients who are sensitive who do not give a skin reaction. In general this type of case can be diagnosed only by careful clinical investigation and then not too exactly. A special type of nonallergic skin was pointed

out by Schloss,⁸ O'Keefe,⁹ and others in the instance of a child who has intestinal allergy.

A number of years ago, I obtained the following data, which add concrete evidence in clinical form for the assumption that intestinal cases do not always react with positive skin tests. A pair of twins that I had occasion to study were weaned from the breast and put on a milk formula. One twin developed urticaria and the other vomited and had diarrhea. The child that developed urticaria gave a positive skin reaction to milk, beef, beef serum and egg. The other twin persistently gave negative reactions to all proteins over a period of many months of intensive study. Tests were repeated in as many as twenty different parts of the body but the results were always negative. However, clinical evidence for the sensitivity of this child, despite the negative skin reactions, was obtained when egg and beef juice were given, which caused vomiting and diarrhea.

Thus I believe that there is in infancy a gastrointestinal disturbance which is specifically allergic but that in such cases skin tests give negative results. I could cite more cases but none so specifically controlled as that of the twins.

Two other methods for doing skin tests might be mentioned. One method is that of Bloch,¹⁰ in which the test substance is applied directly to the intact skin, the area of application being covered with a piece of linen held in place with adhesive tape. The skin reaction is observed from twenty-four to forty-eight hours later, a positive reaction producing definite redness and swelling.

The other method of importance is that introduced by Matthew Walzer,¹¹ which is a modification of the Prausnitz-Kustner method. Blood is drawn from the sensitive child. The blood serum is then injected into the normal skin of the parent, and then the regular protein tests are done at these sites of injection. Positive reactions may be obtained in the normal individual as a result of this passive transfer.

Both of these methods are, I believe, of great importance for experimental investigations. They are limited, however, in their general usefulness and cannot supplant the scratch and intradermal methods.

Summary of Skin Testing—Skin testing cannot be regarded superficially as a simple procedure. A scratch and a bit of protein do not solve the problem. It is an arduously detailed procedure which must be carefully controlled. One must always bear in mind individual variability and the interpretation must be the result of careful weighing of many factors. Despite the limitations, the protein skin test is a method that compares favorably with other diagnostic procedures, such as roentgenograms, Wassermann tests and agglutinin tests, provided it is intelligently interpreted and caution that applies also to the other methods named.

Complete Diagnostic Procedure—Every case is studied with all the available proteins, numbering about 300, extracts of all substances creating dust in the home are used for testing as well as occupational substances that might be brought into the home.

In addition, a complete chemical examination of the blood, cytologic study of the blood, roentgenograms of

the sinuses and chest, Schick Dick and Mantoux tests, and urinalysis are performed. These procedures rule out any secondary factors that may enter into a proper evaluation of a case, such as foreign bodies in the lungs, mediastinal tumors, tuberculosis, metabolic diseases or infections. Thus a nonspecific is coupled with a specific diagnostic procedure.

MANAGEMENT

Elimination—As far as possible I attempt to verify the accuracy of the diagnosis by the elimination of the offending substance or substances. During this strict elimination period many complexities arise, for example, despite careful instructions, egg-containing foods may unknowingly be given to a child who is sensitive to egg. It is not enough to eliminate eggs as such, but one must also eliminate French ice cream, cake, pastry, noodles, icings, and all other foods in which eggs are used. To show how difficult is complete elimination, the following case may be cited. A mother had a child suffering from eczema. This child was sensitive to both wheat and eggs and these substances were eliminated from the diet. For many months the child was free from eczema but recently there had been a moderate recurrence. When the mother was questioned, it was discovered that she had been giving the child Ovaltine, which contains egg. In another egg case it was found that the child ate orange ice, which was later learned to contain raw egg white. And so there are cases of children sensitive to cottonseed who get cottonseed as an adulterant in olive oil, bonbons and other foods, or to nuts which are used in nut pastes and in cookies and cakes, and are not in evidence on inspection.

With asthma due to certain dusts and keratins, it is not sufficient to tell the mother of such a sensitive child to get rid of the substances. It is absolutely necessary to make a thorough canvass of every stuffed article in the house. Instances can be cited of children who had their feather pillows replaced by silk floss or horse-hair. Other beds in the same room or pillows stored in the closets, were found to contain an abundant supply of these substances. The parent of a child who had asthma and was a perennial sneezer insisted that she had completely gotten rid of all feathers in the room and was somewhat obstructive to an investigation of the child's quarters. However, there were found two very small pillows filled with feathers that the boy used on his chair. The elimination of these eradicated his perennial sneezing and asthma. And so with rabbit hair, I had a case of a rabbit hair pillow that was kept in a store room and used on occasions when the child played on the floor.

It is impossible to go into further detail here. It is, however, strongly urged that no stone be left unturned to accomplish the complete eradication of known factors, for only in this way can one be certain that the cause or causes of the child's allergic condition have actually been determined.

Further diagnostic evidence is obtained when specific instances of partaking of an offending substance inadvertently produces an attack or return of the hives or eczema. These instances are clinical proof of the specificity of the inciting factor.

Denaturation of Foods—The elimination of essential foods is something that might result in serious nutritional difficulty. In some cases I have been successful in utilizing these in denaturated form accomplished by the simple process of prolonged heating. For

example, if a child is sensitive to egg white, eggs that are boiled for thirty minutes are often tolerated. With milk, I have found that children sensitive to lactalbumin are almost universally tolerant of evaporated milk. Children have been kept on evaporated milk for as long as a year until tolerance to raw cow's milk could be established.

Spontaneous Desensitization—This type of desensitization is one of great interest. By spontaneous desensitization is meant the instance of the child who because of an intolerance to a particular food, refuses it or vomits it. Only minute amounts of this food will get into his diet, therefore, and in this way a tolerance will be developed. There are many cases of food idiosyncrasy in which this particular natural desensitization occurs particularly with milk and wheat. However, it is never certain in which case this will occur for food intolerance may persist for many years without any spontaneous desensitization and the child will continue to get worse and worse.

Specific Desensitization by Mouth—With foods of a common variety, it is necessary that an increased or complete tolerance be established. Specific desensitization may be brought about by giving carefully graded amounts of the offending substance every day. This is accomplished by carefully regulating the amount of food to be given. For example, if the child is sensitive to milk drop doses or even fractions of a drop, of raw milk are given each day, the dose being gradually increased.

If the child is sensitive to more than one food, the foods may be combined in doses each day, and thus given to the child until tolerance is established.

Desensitization by Injection—Diluted proteins are injected subcutaneously in minute doses, the injection of a dilution being always less than the point of reactivity. For example if a child reacts to a dilution of 1:1,000, the injection of the protein solution should start with a dilution of 1:10,000, in exactly the same manner as with the present treatment of hay-fever.

The injections are given cautiously and the increase in dosage is very carefully guarded. As one proceeds with this method one realizes that a reaction at a certain point indicates that no further increase in dosage should be made until the child no longer shows a reaction to that amount.

The choice of the proper method of treatment for a given case must be guided by the individual peculiarities of each patient.

In the case of simple food sensitization in infancy, the best method is elimination plus oral desensitization. An example of this is the case of a child who at 10 months showed a hypersensitiveness to egg. Eggs in all form were eliminated. For a period of two years raw egg white in increasing drop doses was given, and egg-containing foods were gradually introduced. This child has apparently become desensitized, for at present, and she is 10 years old, she is able to take egg-containing foods without difficulty and is skin negative to egg protein.

On the other hand, a patient came to me at 8 years of age suffering from severe asthma and eczema. This boy was found sensitive to milk and egg. In addition to strict elimination I started desensitizing him by subcutaneous injection with milk and egg proteins. This choice was made on account of the severity of the condition and the prolonged duration of the ailment. After a period of four and a half months his tolerance had reached a point at which he could take small

amounts of these foods. He became skin negative and has remained so to milk and egg over a period of ten years. Six years ago he developed a moderate hypersensitiveness to horse dander after a visit to a farm. Absence of contact with horses has made this factor one of minor importance. During the past year he developed a slight eczema of the face which was due to a new hypersensitiveness which he appears to have developed to wheat and fish, this was easily controlled. He has remained free from asthmatic attacks. It is evident that there is no royal road to any cut and dried cure; one must proceed with these cases always prepared to analyze factors that might be at work.

Severe multiple sensitization is the most baffling form of allergy, and it is futile to hope for any beneficent results to accrue from desensitization. It is necessary to start by rigid elimination of all offending substances, denatured forms of essential foods must be substituted in order to maintain proper nutritional balance. Then gradually attempts may be made to desensitize to one factor after another. This may be exemplified by a child sensitive to at least a dozen foods and several keratins. After painstaking elimination, which required the most complete cooperation of a very intelligent mother, attacks were minimized and for the past four years this patient has been free from all attacks. During these years foods were gradually introduced and increases very slowly made. As I retested the boy very after year, I have found that he became spontaneously desensitized to certain foods such as milk and wheat. After this child had been under my care for seven years, I undertook oral desensitization to other foods to which he was still sensitive, by administering a prepared pellet containing a very minute amount of such foods.

With a case of cottonseed asthma, which I first saw three years ago, the complete elimination of cottonseed—found in mattresses, pillows and overstuffed furniture and cottonseed oil with which the child came in contact through his foods—produced a complete cessation of all attacks for two years. In the third year, since the child still reacted to this protein, I undertook desensitization by injection.

Additional cases observed over a period of years could be cited, but they would not further my purpose. The same specific measures must be applied to the easily handled single sensitivity case and to that of difficult multiple sensitivity. Although the procedure is a complicated one and success difficult to attain it appears to me that much harm is being done by the too frequent resort to nonspecific measures in the hope of making a short cut to a cure.

CONCLUSIONS

A child suffering from the so-called allergic syndromes of asthma, eczema, urticaria and hay-fever must be viewed from the standpoint of protein hypersensitiveness.

A carefully taken and thoroughly analyzed history is essential. This should include not only the history of a typical attack in its relation to foods, contact with animals, season of the year, time of occurrence and locality, but also a broad and general history of the case as a whole.

In addition to the history, a complete physical examination and laboratory tests such as chemical examination of the blood, cytologic studies and roentgenograms should be made and from 300 to 400 protein skin tests performed on each child by the scratch method.

I believe that etiologic factors such as sensitization in utero, sensitization by passage of antigen through the intestinal tract, and sensitization through inhalation of antigenic dusts are of paramount importance.

The management of the allergic child and a study of its progress under the careful regimen described here presents evidence that specific protein hypersensitiveness is as basically important to allergy as the tubercle bacillus is to tuberculosis.

One hesitates to extol the virtues of so complex and still immature a subject as allergy, but an analysis of cases studied over a period of years, I believe, sanctions this presentation as a sound therapeutic procedure.

515 West End Avenue

ACUTE TRANSIENT EPIPHYSITIS OF THE HIP JOINT*

O. L. MILLER, M.D.

CHARLOTTE, N. C.

There is a disease of the hip incident to childhood, which, in view of the frequency of its occurrence, is not given as much textbook emphasis or as much detailed description in collateral writings as it deserves. To distinguish it from acute septic epiphysitis, or septic hip, this condition should be termed acute transient epiphysitis. The clinical course of the latter differs so decidedly from that of the former that I believe it should be recognized as an entity with its own classification. Certainly, a different method of clinical management is indicated.

Much emphasis has been given to destructive septic epiphysitis of the hip, no doubt owing to the fact that it is attended by profound illness and prone to be followed by permanent disability and deformity. Acute transient epiphysitis of the hip as described here causes a child to be sick, creates temporary or permanent deformity depending on the management, and is of a proportionately high incidence. It is not however dangerous to life, nor is serious disability likely to follow its occurrence if the cause of the infection is promptly removed.

My interest in this disease was occasioned by dissatisfaction over the use of the term "acute arthritis" and by a desire for a somewhat more definite diagnosis in certain cases of hip-joint complaint in children. After more careful study of the roentgenograms of the neck of the femur near the epiphyseal line in the so-called acute arthritic hips in children, a rather constant disturbance in bone texture was seen. After noting the clinical course in a number of these patients and following changes about the hip by roentgenogram, I now question very much whether there occurs a primary infectious arthritis of the hip joint in children, beginning within the joint space itself.

The upper femoral epiphysis is a point of unusual physiologic activity and physical stress. The blood is supplied to this area by means of minute, looped vessels passing through a vigorous bone growing center. The hip joint with its multiple motions in an active child is more than ordinarily susceptible to trauma. The character of the blood supply, then, plus even slight trauma invites infectious infarcts or pyemic plugs into this epiphysis with consequent disease.

* Read before the Section on Orthopedic Surgery at the Eighty First Annual Session of the American Medical Association, Detroit, June 27, 1930.

There is now universal interest in more accurate differential diagnosis of the various hip-joint complaints and it becomes an increasing comfort to be able to place each disease or disorder of this joint more promptly into the category to which it belongs. Doing this allows a reasonably accurate prognosis, determines a more or less fixed course of clinical management and gives relief to the physician and the family, if that specter, the tuberculous hip, can be ruled out.

Acute transient epiphysitis of the hip has its highest incidence before 10 years of age. It attacks children who are vigorous and active, and there is little or no prodromal period of indisposition or declining health. Symptoms localize rather promptly to the hip joint and there is sharp muscle spasm, flexion deformity and guarding of the area. Some fulness in the structures about the joint occurs, depending on the extent and virulence of infection and on the amount of exudate in the joint in a particular case. Some of the children complain vaguely for a time and continue ambulatory, others are quite sick when first seen and are unable to bear weight on the affected limb.

Over a period of eight years at the North Carolina Orthopedic Hospital, admissions for various hip diseases were recorded in about the following ratio: tuberculosis, 45 per cent, Legg's disease, 11 per cent, coxa vara of adolescence (admission age limit to the hospital

admission to the hospital was seven weeks. The average admission temperature was slightly more than 100 F., and elevation of temperature was noticed for five weeks. The average leukocyte count on admission was 15,000, with polymorphonuclear cells 81 per cent. The average time of duration of any symptoms, local or general, after admission to the hospital was six weeks. The right hip was found infected in twenty-four cases,

Fig. 1—Multiple small abscesses on metaphyseal side of epiphyseal line mild joint reaction

is 14 years), 4 per cent, acute septic epiphysitis, 12 per cent, and acute transient epiphysitis, 28 per cent. These figures show the comparatively high incidence of the last named disease in an average clinic or practice.

The observations in this paper are based on a study of seventy-seven cases of acute transient epiphysitis of the hip. The average age of the patients has been $7\frac{1}{2}$ years. The average duration of the symptoms before

Fig. 2—Central abscess at epiphyseal line with moderate amount of destruction and joint reaction

the left hip in twenty-four cases, and both hips in three patients. The disease occurs more frequently in males than in females, about 2 to 1.

A definite focus of infection was found in practically every case. One child had a sore on the foot which seemed to be a source of infectious metastasis, and several children had recently had some of the infectious diseases of childhood, but the chief source of infection was found to be the tonsil. Early remission of symptoms followed tonsillectomy in 82 per cent of the patients.

A simple transient epiphysitis should be suspected in a child presented with a comparatively slow developing hip complaint, with the local and general symptoms outlined, when he has diseased tonsils or some other outstanding focus of infection or has recently had one of the infectious diseases. There may be an occasional history of intermittent attacks of lameness in a hardy child before his family considers him sick enough to demand hospital care.

The roentgenogram in this disease is not altogether diagnostic. On first examination in some of the cases of this series, the roentgenograms were interpreted as being negative. In the same cases, a few days later, enough absorption had taken place along the epiphyseal line to allow a reading of destructive change in the bone.

texture and sufficient exudate had accumulated to alter the joint outline. This change in mild cases is not outstanding, in others it is very definite. With small infected infarcts lodging near the epiphyseal line, the amount of destruction resulting depends on the factors of virulence, resistance and protection. Roentgenograms may show a localized abscess or absorption all along the metaphyseal aspect of the epiphyseal line. An abscess may develop, showing lines of absorption down into the neck of the femur, and in one case it tracked to and involved the trochanteric epiphysis. Sometimes the abscess forms on the epiphyseal side of the epiphyseal line and burrows through the head toward the joint. A certain amount of exudate and reaction are present, showing thickening of the overlying joint structures.

Treatment in these cases consisted of rest in bed, traction to overcome muscle spasm and deformity, and removal of infectious foci. The average period in traction for the hospital cases was five weeks. When joint symptoms cleared up, no further restriction was remained well.

placed on the child and weight bearing was soon resumed. The patients treated have been followed a sufficient length of time to determine that they have

No appreciable difference in the length of the legs has been noted and the hips have recovered with normal function. A hip requiring drainage should not be classified as transient epiphysitis.

SUMMARY

Acute transient epiphysitis is a common cause of hip complaint in children. It is usually provoked by mild

Fig 3—Abscess inner aspect of neck of femur at the epiphyseal line with considerable destruction of bone and joint reaction.

Checking these hips by roentgenograms in follow-up work showed the femoral heads becoming a little more gross in appearance as compared with the normal, and the neck slightly thicker and broader. The head shows an increased superior-inferior diameter, particularly in the outer aspect. This gives one the impression of growth stimulation by low grade infection near a growing center.

Fig 4—Abscess formation outer aspect of neck of femur at epiphyseal line with joint reaction and infection tracking to trochanteric epiphysis.

trauma. It may be suspected in a child complaining of pain about the hip if he has diseased tonsils or has recently had an acute infectious disease. Eighty per cent of my cases were associated with diseased tonsils.

Carefully made roentgenograms will show small abscess formation and absorption about the epiphyseal line.

The treatment consists of the removal of infectious foci, rest from weight bearing, and traction on the lame limb.

Duration of the disease is from a few weeks to a few months and if prompt treatment is instituted, children recover without any disturbing changes in the hip joint.

15 West Seventh Street

ABSTRACT OF DISCUSSION

Dr. PHILIP LEWIN, Chicago. It is probable that many of these cases have been overlooked principally because they have not been looked for. Dr. Miller has been looking for them and has found seventy-seven cases. When one considers his figures of all hip cases examined during this period, acute transient epiphysitis occurring in 28 per cent, one may be certain that many are being overlooked. The profession is indebted to Dr. Miller for a term that will take out of the large classification of hip conditions a certain definite condition and put it in its own little 'cubbyhole.' In every branch of medicine this is an

evidence of progress. I want to emphasize a few points that I believe deserve discussion. The first point is the necessity of a careful history, the second, the importance of a complete examination, and the third, the examination of the roentgenograms. One should especially examine the epiphyseal line, both sides of this line, particularly the diaphyseal side of the epiphyseal line, where most pathologic changes occurred in Dr. Miller's cases, although in a few cases it was found on the epiphyseal side. If more roentgenograms were examined with this region in view and with a magnifying glass, I think many would be discovered. It seems that there is an analogy here between acute transient epiphysitis and osteomyelitis, which as every one knows, in the early roentgenograms is usually negative and in these cases, most of which were seen by Dr. Miller at the end of five, six or seven weeks the same was true. From Dr. Miller's diagrams, which are excellent especially for teaching, it seems as though the location of these infected emboli, whether they come from the tonsils, as seems evident from his statistics or not, seem to go a little bit farther than those which produce osteomyelitis. Laboratory studies are important, as are special tests such as the tuberculin tests. Dr. Miller didn't tell the incidence of the positive or negative tuberculin tests, and of the Wassermann tests. He emphasized the fact that the child should be treated by recumbency in bed with traction as well as the eradication of foci of infection. I should like to ask Dr. Miller to tell in closing what was the incidence of positive tuberculin tests in the seventy-seven cases, what was the percentage of the positive fabere sign which is said to be a definite test for hip conditions, and, thirdly, what is the prognostic value of the fabere test during treatment?

DR CHARLES W. PEABODY, Detroit. It is my idea that something probably of great value is being added by Dr. Miller to the knowledge and classification of disturbances of the hip joint in children. In some ways the paper is a little difficult to discuss because it contains or tends toward a somewhat speculative or theoretical point of view and resolves itself, I think, into two propositions. One is that there is a clinical entity representing an inflammatory process in the hip which is localized in the epiphysis, with a gradual onset, which does not go on to necrosis or suppuration and which recovers under conservative treatment with some growth disturbance, but sometimes the roentgenograms show a normal condition. His illustrations bring a good deal of supportive evidence to that proposition. I am sure that I have seen a number of hips with a subacute onset, that I strongly suspected of being tuberculous, that had something just a little queer about the appearance of the head or neck of the femur along the epiphyseal line but didn't seem at the early stage to justify exploration, and on the giving of a trial of conservative therapy, cleared up rather rapidly and permanently instead of relapsing as they probably would have, had they been tuberculous, and did not go on to more high grade inflammatory condition. The other proposition in his paper is this: An absence in the hip joint of any nontuberculous synovitis that does not start with a primary epiphysitis brings up the question, Why should the hip joint be different from other joints in the body in being free from infective synovitis or arthritis? Or are all monarticular nontuberculous and nonsuppurative joints in children really epiphysitis? I do

not find it so easy to agree with this part of Dr. Miller's proposition, and eliminate from the classification infective arthritis in the hip. The anatomy of the hip joint does suggest that it may be less likely to contain an inflammatory process restricted to either the synovial membrane and cartilaginous surfaces on the one hand, or the epiphyseal cartilage on the other. I think it is one of the few joints in the body in which the epiphyseal cartilage is included entirely within the joint capsule and is in contact with the synovial fluid, so that in itself may support his proposition that the synovitis is secondary in all cases to epiphysitis.

DR HERMAN C. SCHUMM, Milwaukee. I made a survey of all the infectious hip conditions that have been seen at the Children's Hospital in the last five years. There were eighty-four cases of hip joint condition and seventeen of these could be classified under the title that Dr. Miller has expressed. I was able to get a few of these patients back for examination and to

make roentgenograms when they did come back. In going over the histories, there were a few things that stood out. First, that there was one group, a rather small one (in fact, six in number), in which the children were rather young, none being over 7, in which there was a definite history of trauma without any definite foci of infection. When children are admitted they are usually gone over by the various services, notes are made and I could not find on any of these notes that there were any foci of infection. The course of the disease in these cases was somewhat different from the others, that is it cleared up much quicker with treatment—rest and traction. All six cleared up with apparently perfect functional results in from one to two weeks. As to the other group of eleven patients, the condition in seven of the children cleared up without any demonstrable trouble in the joint, in four it progressed that is, the children had a destructive lesion in the head that slowly progressed and finally became a decided deforming factor. The children were about equally divided as to sex. Among seventeen children, eight were girls. The cases that cleared up without any deformity were cured within a period of five weeks. In one of these cases I was able to aspirate pus, in others no attempt at aspiration was made. In the one in which pus was aspirated there was no subsequent drainage. As far as the blood picture

Fig. 5—Abscess on the epiphyseal side of the epiphyseal line burrowing through the head causing general reaction inside and outside the joint.

went, I could find nothing definite. Some of the more severely ill patients did not have a very high leukocytosis, although they appeared most sick. Some of the others had a leukocytosis varying from 10,000 to 25,000. In the first group of six children the temperature did not exceed 101 F in any case. In the group of eleven children the temperatures varied from 101 to 103.5 F. The thing that impressed me was that in going over the roentgenograms I found that all the cases were apparently negative with the exception of the four that showed this destructive lesion.

DR D. B. PHENISTER, Chicago. I should like to raise a point with reference to nomenclature. Lesions located on the shaft side of the epiphyseal line are usually spoken of as metaphyseal and those primarily on the epiphyseal side as epiphysitis. If most of these lesions begin on the shaft side, that term should not be included.

DR GUY A. CALDWELL, Shreveport, La. I should like to ask Dr. Miller two questions. The first is whether he made a

practice of aspirating these joints for diagnosis. I think that, when a child is admitted with a fever of 101 F or more, the white blood cells and the polymorphonuclear percentages increased and the joint distended with fluid, the condition warrants aspiration of the joint to determine whether or not pyogenic organisms are present and whether or not the character of the fluid is essentially purulent. I should like to know also at what stage and from what data he decided that conservative treatment should not be continued and that drainage was necessary. I have regarded cases with the clinical picture that he has described as being in reality osteomyelitis of the neck of the femur. The neck of the femur is in fact the upper extremity of the diaphysis. A suppurative focus developing in the neck of the femur adjacent to the epiphysis follows, therefore, the general rule that osteomyelitis originates in the diaphysis near the epiphysis and differs simply because the upper portion of the femoral diaphysis is included in the capsule of the hip joint. A suppurative process that extends to the bone surface in this region necessarily spreads by way of the epiphysis and gives rise secondarily to a suppurative arthritis of the hip joint. Since I have regarded such cases as osteomyelitis of the neck of the femur with secondary suppurative involvement of the hip joint I have made a practice of aspirating the joints, and when the aspirated fluid had the gross appearance of pus and showed pyogenic organisms in the smears when examined microscopically I have drained the hip joint by incision and have usually obtained a good result. I cannot say whether or not the same joints would have subsided without drainage because I have always accepted the presence of frank pus in a joint as an absolute indication for drainage and have not tried conservative measures.

DR CHARLES LEROY LOWMAN, Los Angeles. I should like to ask Dr Miller whether he has attempted to clear up the roentgenogram by photography in a variety of positions, in rotation and extreme flexion. In regard to interpretation of roentgenograms I have found that by using a pair of high powered field glasses and standing off 8 or 9 feet from the illuminating box I can get a definition that I cannot get in any other way.

DR J ALBERT KEY, St Louis. I have operated on two of these patients rather recently and found low grade minute streptococci in the culture. Another thing that was interesting was that the tissue which I removed and examined from these smaller foci in the epiphyseal line closely resembled a giant cell tumor.

DR HENRI W MEYFORD, Rochester, Minn. In examination of the x-ray plate these conditions have often been noted as described by Dr Miller. There has been difficulty, however, in recognizing and interpreting the roentgenogram. By cutting down the amount of light behind the plate, then holding the plate at an angle of from 40 to 60 degrees one can bring out these areas much more easily. A low grade osteomyelitis or possibly the beginning of an inflammatory lesion which might lead eventually to a giant cell tumor is being dealt with. It makes me think of the types of osteomyelitis sometimes seen a sclerosing type and a rarefying type, and again the types that go on to a solitary cyst.

DR OSCAR L MILLER, Charlotte, N C. Dr Lewin's question about the Wassermann test may be answered by saying that the Wassermann reactions were negative in this series of cases. The Pirquet tests were in the main negative, but I have not recorded the fact. That was an oversight. I don't know that I would have known how to interpret skin test observations. The false sign I don't know about at all. In regard to the question as to when they are well of course I am running traction when they are guarding the joint when I feel they are not guarding it. I remove the traction and allow freedom of the bed. If the child doesn't start protecting it again he goes on crutches and if that doesn't provoke disturbance I give him a little more freedom and let him go home. Dr Parody raised a question in regard to other joints. I think it is quite possible that the arthritis in some of the other joints might start within the epiphysis also. I think that is true of many other joints I have seen but I am sticking to the hip joint in this paper. The literature that helped me most in coming to my conclusion was the work of Karger on Bone Infections. He seems to lead all writers a little bit in his conception of how infections start and

travel along working under the periosteum and dropping into the joints. Dr Phemister's question about nomenclature is pertinent. I allowed myself to call this 'epiphysitis' because it seemed to be primarily, or very early secondarily, the epiphysis that became involved, so in lieu of a better name I have called it 'epiphysitis'. Dr Caldwell raised the question about when to operate and when not to operate. I never had a provocation to operate on any of these patients. In one of them, the sickest of the children I aspirated and it was a dry tap. I think that the septic joint tells its story pretty rapidly, so one does not have to worry about those one is going to drain and those one is not going to drain. It is a question of surgical judgment that evidences itself fairly quickly. These children come down a little slower than patients with a septic joint, the differential diagnosis from tuberculosis I won't go into. That is a study that is made in the ward. Everything at one's command is tried to arrive at an early and definite diagnosis of joint tuberculosis and then one fails on some of them. I have not tried the different positions of the hip that Dr Lowman suggested in getting roentgenograms. That should be interesting. I am interested in the question of organisms. I have no studies on that point as I felt the joint might be damaged in getting material.

THE TROPICAL RAT MITE, *LIPONYSSUS BACOTI* HIRST, 1914

THE CAUSE OF A SKIN ERUPTION OF MAN,
AND A POSSIBLE VECTOR OF ENDEMIC
TYPHUS FEVER*

BEDFORD SHELMIRE, MD

DALLAS, TEXAS

AND

WALTER E. DOVE, ScD

CHAPLSTON, S C

The present paper reports that in northern Texas an acarus of the human skin is caused by bites of a blood-sucking rat mite (*Leio gnathus*) *Liponyssus bacoti* Hirst. Attention is invited to the history of the parasite, to the types of lesions caused by bites of the mites, and to attempts to correlate the presence of these mites with the occurrence of endemic typhus fever.

HISTORICAL

The tropical rat mite was first recorded from rats in Egypt. In 1913 specimens of the mite collected at Assuit, Egypt were described by Hirst¹ as *Leio gnathus bacoti*. A few months later other specimens were obtained from Egypt, Abyssinia, Australia and Argentina. The latter specimens were recognized by Hirst as the same species. For them he considers the brown rat *Mus norvegicus*, as the principal host.

The tropical rat mite was first reported² as a blood sucker of man at Sydney, Australia. Specimens were obtained from man from the walls of a boot factory and from a bed made by rats. In that city the mites were also reported as attacking workers in a seed store and causing considerable irritation to the skin.³ In cities of western Australia specimens of the mites also were found on man.

In the United States this species made its appearance in 1921. Bishop³ reported that they were extremely

Read before the Section on Dermatology and Syphilology at the Eighty-first Annual Session of the American Medical Association, Detroit, June 26, 1930.

annoying to man in the vicinities of Dallas and Fort Worth, Texas. They were troublesome especially in business buildings. Persons in department stores, grocery stores, a railroad office, a motion picture theater, federal buildings, and houses adjoining restaurants were annoyed by bites. In one office building the parasites were present on the tenth floor. Bishopp attributes the advent of the mites to migrations of rats and to the tremendous increase in their number during 1920 and 1921.

INCIDENCE AND ORIGIN OF 'RAT MITE DERMATITIS'

Approximately three years ago, three members of a family consulted one of us (B. S.) for a skin eruption which had been diagnosed as scabies by a local physician. When these persons reported to us the eruption had not been influenced by various forms of sulphur medication. The dermatitis presented by the father and mother might easily have passed for a mild infection of *Sarcoptes scabiei*. The third member of this family, a girl, aged 18 months, presented a diffuse, extremely pruritic, papular eruption over the body with secondary excoriations and pustules. On the face, neck and scalp a few scattered papules were present. The

Fig. 1—Dorsal and ventral view of a female specimen of the tropical rat mite.

latter finding eliminated the possibility of scabies. A search of the patient's apartment revealed a heavy infestation of mites. Specimens were collected and identified by one of us (W. E. D.) as the tropical rat mite, *Liponyssus bacoti*. They were found on the walls of the room, on the bed of the child, and on the child's body. Many of them were engorged with blood. Inquiries revealed the fact that five additional families of the apartment house were affected with bites of these parasites. Since then, as many as 200 additional cases of this acarosis have been brought to our attention. Approximately 100 persons reported for treatment of the skin, and as many reported by telephone to the United States Bureau of Entomology. The frequent occurrence of cases of the condition caused us to adopt the popular name "rat mite dermatitis." According to the case histories there was a wide variation in the kinds of places where bites were received.

Theaters—In our private practice (J. B. Shelmire and Bedford Shelmire) women were seen who had visited a local motion picture theater. On them there were groups of papular and urticarial lesions, which were confined to the backs of their thighs and legs. An investigation of the theater revealed an infestation of tropical rat mites. The building was fumigated with hydrocyanic acid gas, with the result that cases ceased

to be seen at our office. Several months after the fumigation other persons having evidences of such bites were seen at our office. Some of them had visited the theater that had been fumigated, and others had visited another theater in the same neighborhood. We were impressed with the origin of the bites of these persons. It seemed that the semidarkness of the picture theater was favorable for the mites to bite. We made inquiry of Dr. J. C. Michael of Houston, Texas. He states that he has seen about a dozen cases of eruptions of this type in which there was a history of visits to motion picture theaters. Bedbugs were excluded in all instances.

Baylor Clinic—In the clinic building of Baylor Hospital a mild infestation of tropical rat mites caused five nurses and twelve patients to present evidences of bites from these parasites. The mites were found in the drawers of a desk and on the walls near hot water pipes. In the department of bacteriology, some distance from the clinic building, the mites were present during the spring months of the past two years. Three workers in this laboratory presented evidences of bites and called attention to the painful sensations that were produced by the feeding of the mites. When such sensations were felt, these men were able to find the mites and to remove them from their bodies.

Department Stores—In several instances, rat mites have bitten the employees of department stores. During a period of three months, nineteen girls working in one department store were seen with such skin eruptions. The bites were received shortly after a large number of rats were trapped or poisoned. When rats were destroyed the mites were forced to find other hosts for their meals of blood. The bites on persons often follow campaigns for destruction of rats. We have observed them on workers in seed stores, hardware stores, a shoe shop and a restaurant.

Private Dwellings—Our observations indicate that in Dallas the mite is well established in many residences and apartments. At some of the locations, persons have been annoyed during successive years. At other locations living quarters are vacated on account of the mites. In one instance the mites caused five families to move from an apartment hotel. These vacancies resulted in a loss of rent which amounted to \$1,000. The loss represented 20 per cent of the income of the hotel for a period of three months. It is seen that the rat mite problem is one of economic importance as well as one of interest to physicians and biologists.

During the past three years, approximately fifty persons affected with the bites of rat mites were seen in private homes. From telephone calls requesting information on these parasites we estimate that as many more persons did not report to physicians. In our opinion about one half of the number of persons received bites in the vicinity of their homes. Some of the patients found the mites when biting sensations were felt and were able to submit specimens for identification. Others did not suspect mites as the cause of the skin eruption and did not look for them. When mites were not found by the patients, we made visits to their residences. At such locations we were often able to find the mites on the walls of the rooms. They were found in the bath room or kitchen but were present in other places where heat was furnished. During low atmospheric temperatures they were found on the walls near lighted stoves.

When persons were suspected of having "rat mite dermatitis" and we were unable to find mites on the premises of the home or about the places of work,

inquiries were made regarding the presence of sparrows, chickens and other animals. There was seldom any indication that mites of such birds, fowls or animals were concerned in causing the skin eruption. The histories of these cases were correlated with the presence of rats. In some instances rats had been trapped or poisoned. In other instances the mites apparently came from beds abandoned by young rats. From these and other observations we consider rat mites as incidental parasites of man.

Out-of-Town Cases—A tentative diagnosis of "rat mite dermatitis" was made on eighteen persons residing outside the city of Dallas. In one of these cases the provisional diagnosis was confirmed by finding mites. One of us (W. E. D.) visited a patient from Sherman, Texas, and found mites on the walls and floor of the residence. The mites were identified as *Liponyssus bacoti* Hirst. Five of the other seventeen patients found mites on themselves or in the home but did not send in specimens for identification. The tropical rat mite has been obtained at Sherman, Longview, Henderson, Dallas, Plano and Fort Worth, Texas. From these collections and from the reports of bites it appears to be well established in northern and eastern Texas.

TYPES OF ERUPTIONS

On adults the primary lesions of rat mite bites are small urticarial wheals and papules varying in size from that of a pinhead to that of a split pea. The former lack the central hemorrhagic punctures that are considered characteristic of the bite of the bedbug, *Cimex lectularius*. On young children papules, urticarial welts and frank vesicles are often present. The vesicles are not confined to the hands and feet as in scabies but are diffusely distributed on the affected portions of the body. In the more diffuse eruptions the severe pruritus causes the patient to scratch and this results in secondary excoriations.

On adults the lesions are usually few in number. Often there are no more than six to twelve lesions grouped about the ankles or on the trunk. Rarely, an adult presents generalized evidence of mite bites. In some of the homes where infants were bitten by mites the adults showed less evidence of the bites. They were annoyed so little that they did not volunteer the information until they were examined. In both adults and infants there is a definite tendency toward grouping of the bites. This is attributed to the piecemeal feeding of the mites.

The sites of predilection are not only those portions of the body which come into contact with the mites but also the areas having clothing to press on the mites. In addition to the face and hands of children lesions are found about the ankles, belt line, upper shoulders and neck. On women visiting motion picture theaters lesions occur on the flexor surface of the lower part of the thighs and the upper part of the legs.

In diagnosis, rat mite dermatitis must be differentiated from scabies, pediculosis corporis, and bites from chiggers, bedbugs, fleas, grain mites and other blood-sucking insects. In children having vesicular lesions the eruption must be differentiated from chickenpox. In one of our patients a little girl of 18 months the lesions resulted in a quarantine for chickenpox until it was proved that the intensely pruritic eruption was due to the bites of the tropical rat mite. Scabies and pediculosis can usually be excluded on clinical grounds, but in other cases a differential diagnosis depends on the recovery and identification of the mite.

IDENTIFICATION OF MITES

The adult female is illustrated in figure 1. It has definite characters which enable one to identify it. It is more easily identified when the specimen is cleared. In order to avoid the possibility of confusing this species with mites which breed in decaying wood or vegetable matter, or with at least two species of fowl mites, *Liponyssus sylvaticum* and *L. bursa*, it is suggested that specimens be sent in for identification. Living mites may be placed in dry vials with small bits of paper. The vials should be well corked to prevent the escape of any of the mites. In selecting specimens for identification, it is desirable to obtain the adult females. They are much larger than other stages of this species. When engorged with blood they are rather clumsy in crawling and are easily transferred to vials with a camel's-hair brush.

Fig. 2.—Papular lesions from mite bites limited to the back and neck.

HABITS AND LIFE CYCLES OF MITES

When the female mites engorge with blood, they do not remain attached to the skin. They may remain in the hair of rats for several hours, but usually they leave the host and seek cracks, crevices or other protected places. They prefer dark locations where there is no moisture. In such locations a female having a single meal of blood may deposit from three to eight eggs. The eggs hatch in about four to six days. If within twelve days the young mites are unable to find a suitable host, they die of starvation. If the period of incubation is added to the period of longevity of newly hatched mites, it is seen that a period of about eighteen days is necessary for incubation of the eggs and starvation of the young mites emerging therefrom. This means that, following the destruction of all rats, a period of about eighteen days must elapse before the

mites will all have perished of starvation. It is possible that starvation of the nymphal stages of the mites may require slightly longer periods. The female mite is capable of living approximately ten days without feeding.

The newly hatched mites attach to the skin of the rats or mice for approximately two days. Some of them may be observed on the eyelids, feet and thighs of the animals. From many locations on the body, the rat is able to remove the mites by scratching and to devour them. When newly hatched mites become engorged with blood they drop from the animal. At a later time they molt their skins. Following molting they reattach themselves to an animal for another meal of blood. There are apparently four or five feedings and three or four moltings before the larvae attain

Fig. 3—Papular lesions from mite bites grouped at the belt line

maturity. Such engorgements may take place on one animal or on different ones.

On man a mite may obtain a meal of blood from several places. The piecemeal feeding may be attributed to the disturbance of the mites, or to the fact that man is an abnormal host.

ENDEMIC TYPHUS, OR BRILL'S DISEASE

There is endemic in certain sections of the United States a disease which resembles typhus fever and gives positive Weil-Felix reaction in high dilutions. Most of the records of cases are from the Atlantic seaboard and Gulf ports. The cases occur in mild epidemic or sporadic form, run a definite febrile course of approximately two weeks and are accompanied by a characteristic erythematous macular and petechial cutaneous eruption. The American form of the disease differs from Old World typhus in its relative mildness and

in certain well marked epidemiologic characteristics. The former is clinically indistinguishable from the mild typhus occurring during interepidemic periods in the Old World and Mexico. According to Mavey,⁴ the North American strain seems to be derived from the Old World source. In contrast to Old World typhus, there is evidence that the disease is not transmitted from one person to another by the body louse. In the United States there is a summer and fall incidence, and the disease does not seem to be communicated directly from one person to another.

Mavey, an outstanding authority on endemic typhus, or Brill's disease, believes that "a reservoir for the disease may exist other than in man, a rodent reservoir with accidental transmission to man through the bite of some parasitic blood-sucking insect or arachnid. The rodents upon which suspicion immediately falls are rats and mice, and the parasitic intermediaries which are first suspected are fleas, mites, and possibly ticks." He bases this hypothesis on "(1) the uneven focal distribution of the disease, (2) its sporadic occurrence, (3) its apparent lack of direct communicability from an infected person, (4) its association with the place of business rather than with the home particularly with those premises upon which foodstuffs are handled or stored, (5) the reoccurrence of cases on the same premises after considerable intervals of time, and (6) its seasonal incidence."

POSSIBLE RELATIONSHIP OF THE TROPICAL RAT MITE TO ENDEMIC TYPHUS

With the occurrence of "rat mite dermatitis" in northern and eastern Texas, endemic typhus fever, or Brill's disease, made its appearance. The coincidental advent of the disease and of the parasite causes us to question whether or not there is a possible relationship between them. Reports have been received of the occurrence of 11 proved and 125 probable cases of the disease. This section of the present paper reports the occurrence of *Liponyssus bacoti* in four localities furnishing proved cases of endemic typhus. It reports some evidence of "insect" bites previous to the onset of endemic typhus.

Cases at Dallas and Fort Worth—During the past year six cases of endemic typhus were reported at Dallas. They were clinically typical of the disease and the blood samples gave a positive Weil-Felix reaction in high dilutions. Three additional cases originating in the vicinity of Fort Worth proved to be typhus. At both Dallas and Fort Worth the tropical rat mites have been of economic importance and of medical interest. Of a large number of persons receiving bites of the mites who reported for treatment of the skin eruption we do not know of any who developed symptoms of endemic typhus. However we were able to question only a small number of our patients regarding illness subsequent to their cutaneous eruptions. We would expect only a small percentage of the mites to harbor the organisms of endemic typhus. In Old World typhus only the infected lice are capable of transmitting the disease.

The persons affected with endemic typhus at Dallas and Fort Worth did not recall having been bitten by insects. Two of these persons assisted us in examinations of their places of business. In these locations we were able to find rats infested with *L. bacoti* and rat fleas.

⁴ Mavey, K. F. Typhus Fever in the United States. Pub. Health Rep. 44: 1735-1742 (July 19) 1929.

Cases at Gilmer—During the past year clinical symptoms indicated that five cases of endemic typhus occurred in the vicinity of Gilmer, Texas. Also, blood samples drawn from two of these persons during their illness gave a positive Weil-Felix reaction in high dilutions. In the proved cases the patients did not recall whether or not they were affected by "insect bites." A visit was made to the bakery that was operated by these persons. Beneath the floor of the bakery a large number of rats were present in the ground. As yet we have been unable to trap these rats or to obtain parasites from them.

Cases at Longview—From talks with physicians in the vicinity of Longview, Texas, it appears that many cases of endemic typhus were diagnosed as "short typhoid" or "unknown fever."

Since one of the proved cases of endemic typhus reported at Dallas from Longview, a questionnaire regarding this disease was sent to Dr. C. C. Adams of that city. He reported that during the past three years he has seen approximately fifty cases of what he now believes to be Brill's disease. His last case was the only one tested for the Weil-Felix reaction. According to the report, all the cases had negative tests for typhoid and paratyphoid fever. The blood counts were somewhat higher than in typhoid, but sometimes as low as would be expected in typhoid. About the fifth day a rash came on the skin of some of the patients. The lesions were more marked and considerably more numerous than the

rose spots of typhoid. Rigors were nearly always present early in the disease. As compared with typhoid, the bronchial symptoms were more common, pain was more severe, and nervous symptoms were more marked. Occasionally there was considerable embarrassment of the heart and a faster pulse. Until recently Dr. Adams believed that these were cases of paratyphoid of a strain that was not represented in the triple vaccine. With such a vaccine he was unable to get immunity for this disease. About ten of his patients were administered the triple vaccine within from six weeks

were received in the room of a hotel. When the bites were felt he made a search for bedbugs but was unable to find them.

Inquiries were made of the city manager of Longview. According to him, approximately 100 cases occurred there during the past three years. He says that the cases had a course of fourteen days almost to the day. His records show that the greater number of cases occurred during August, October and November. During the early half of last November the cases were as numerous as those of any preceding month. His records indicate also that cases occurred among the workers of at least two stores. Five persons working in a grocery store from March 23 to Aug. 31, 1929, were affected with the so-called unknown fever.

Rats were trapped in stores at Longview and from them we were able to recover specimens of the tropical rat mite. The rats examined were infested also with fleas.

Cases in Other Towns—In other towns within a radius of 25 miles of Longview, cases of "short typhoid," or "unknown fever," were reported. At Henderson, Texas, at least seventeen patients reported for treatment during the last calendar year. Rats obtained in this locality were found to be infested with tropical rat mites and rat fleas. Some of the towns reporting cases of the fever were not visited by us.

WEIL-FELIX TESTS ON PERSONS RECOVERING FROM ENDEMIC TYPHUS

Following the recovery of five persons with proved infections of endemic typhus, samples of blood were drawn and the Weil-Felix tests were repeated. The latter specimens were sent to Dr. R. E. Dyer, Hygienic Laboratory, Washington, D. C. Two of the samples represented patients who gave positive reactions in dilutions of 1:160 during their illness. Approximately six and eight months after illness the blood samples gave positive reactions in dilutions of 1:40. Samples of blood obtained from two other patients during illness gave positive reactions in dilutions of 1:640. Four and eight months after illness the latter cases were negative for similar tests. A fifth patient, whose blood gave a positive reaction of 1:320 during illness, furnished a sample of blood two months later which gave a negative reaction. From the tests on persons recovering from endemic typhus it appears that the agglutinins are present in the blood stream only for short periods.

The results of the tests on proved cases of endemic typhus were similar to tests made with blood of persons suspected of having endemic typhus at Gilmer and Longview. From these localities nine samples of blood

Fig. 4.—Typical grouping of bites on the lower part of the leg. The patient also had a few isolated lesions over the body.

Fig. 5.—Mite bites scattered diffusely over the body, face and scalp. As many lesions were vesicular the eruption closely resembled chickenpox.

to six months before they became sick. The duration of his cases was from ten to fifteen days. From these patients no specific inquiry was made regarding insect bites prior to the onset of the illness. In the proved case from Longview there was a definite history of insect bites seven days before onset of the illness. Serum of his blood was positive for the Weil-Felix test up to 1:640. According to him, the bites

were obtained from persons several months after their illness. Five of these were negative for the Weil-Felix tests and four of them were positive in dilutions of 1:20 and 1:40. (The positive reactions in dilutions of less than 1:80 are not considered diagnostic of this disease.)

COMMENT

The occurrence of tropical rat mites at Dallas, Fort Worth, Henderson and Longview, Texas, show a coincidental occurrence of these parasites with proved cases of endemic typhus. The history of "insect bites" of one of the patients would seem to strengthen the hypothesis of insect or arachnid transmission of the disease.

According to Bishopp,³ the tropical rat mites occurred at Dallas just after there were migrations of large numbers of rats from the South. Since the rat mites and endemic typhus were found in this section after the migrations of large numbers of rats, one is inclined to attribute the advent of the new parasite and of endemic typhus to these migrations.

Since the report of the occurrence of tropical rat mites in Australia, it is interesting to note that small numbers of mild sporadic cases of endemic typhus have been reported by Howe⁴ of Adelaide, Australia.

SUMMARY

1 Approximately 200 cases of "rat mite dermatitis" are reported from Dallas, Texas, and neighboring towns.

2 From persons having evidence of mite bites and from their residences or places of work, mites were collected and identified as *Liponyssus bacoti* Hirst.

3 At Dallas, Fort Worth, Henderson and Longview, Texas, mites were collected from rats and were identified as *Liponyssus bacoti*.

4 At Dallas, Fort Worth, Henderson and Longview, 11 proved cases and approximately 125 cases of suspected endemic typhus are reported.

5 From tests on persons recovering from endemic typhus it appears that agglutinins are present in the blood stream only for short periods of time.

6 The advent and coincidental occurrence of endemic typhus and the tropical rat mite in northern and eastern Texas suggest that these parasites may be vectors of the disease.

ADDENDUM—Since July, 1930, nine proved cases of endemic typhus have been seen at Henderson and Longview, Texas. From locations suspected of being the origin of these cases, we obtained tropical rat mites and rat fleas. An account of the studies with these parasites will be published in a later paper.

ABSTRACT OF DISCUSSION

DR. CLARK W. FINNROD, Chicago: I am sure we all feel confident that we should recognize this dermatosis should these rats and their parasites migrate to our respective communities. When confronted with a clinical picture simulating scabies, pediculosis or the bites of other parasites, not being able to demonstrate their causative organism, we shall now be on our guard for a traumatic and urticarial dermatitis, the result of bites of the tropical rat mite. The most important aspect of this communication and study is of course that portion which does not concern the dermatologist alone and which as yet is a speculation. I refer to the etiologic relationship of this parasite to endemic typhus.

DR. JOHN E. LAKE, New Haven, Conn.: I should like to know how often, if ever, the itch mite has been recovered in these cases.

³ Howe quoted from Stitt, F. R. *Diagnosis and Treatment of Tropical Diseases*. Philadelphia: P. Blakiston's Sons & Co., 1929.

DR. R. R. SPENCER, Washington, D. C.: I should like to know whether there was fever with the dermatitis, and whether the authors think this has any relationship to typhus fever, and if in the typhus fever patients there is a definite history of bites before the onset of the fever. We in Washington are greatly interested, for we suspect that the tick has something to do with typhus fever. All through the South and particularly in Washington, we get definite histories of typhus fever following tick bites.

DR. BRADFORD SHELMIF, Dallas, Texas: Regarding the question of Dr. Lake, the skin irritation is caused by the bites of the blood sucking mites and is analogous to the bites of the mosquito or other blood sucking insects. After the mite becomes engorged with blood it drops from the human body to hunt some crack or crevice. The skin symptoms of the individual infested with these mites are not caused from the migrations of these mites within the skin as in an acarous scabies infection. Dr. Spencer asked about fever in connection with the bites of these insects. When bites are very numerous the patient may show a transient fever for a day or two. This was noticed in the case of a little girl quarantined for chickenpox and in two girls working in the Dallas branch office of one of the large mail order houses. In the latter instance the two victims showed large numbers of bites and the accompanying fever caused the nurse in charge to send the girls home from work. This mild fever is analogous to that often displayed by a patient with a large number of chigger bites and is not a manifestation of typhus. It is of toxic and not infectious origin.

OSTEOMYELITIS VARIOLOSA

REPORT OF THREE CASES*

C. F. LIKENBARY, M.D.

AND

JOHN F. LeCOCQ, M.D.

SEATTLE

The ordinary acute osteomyelitis is sometimes one of the complications attending cases of variola. That it does not occur more frequently than it does is rather surprising, in view of the fact that smallpox is usually accompanied by more or less suppuration. This ordinary acute osteomyelitis complicating variola will not be discussed in this paper.

However, that smallpox can produce another type of osteomyelitis, nonsuppurative in nature, now seems to be a well established fact. In the obscure deformities, inequality in the length of the upper or lower extremities, it is well to inquire carefully whether variola has preceded the onset of the clinical manifestations of the deformities.

PATHOLOGY

Since the descriptions of Chiari and Mallory, little has been added to the literature dealing with the pathology of this condition.

Chiari¹ in 1893, made a report of the observations in twenty-two cases of smallpox that had come to necropsy. These patients had died during the three different stages of variola. In 86 per cent of the cases disseminated foci were found in the bone marrow, and these foci had definite variolar characteristics. But these foci did not show any evidence of suppuration. In one case which came to necropsy two months after smallpox, he found that there were still evidences of isolated, nodular, pale foci in the bone marrow. The obliterated structure of the bone marrow was being replaced by granular

* Read before the Seattle Surgical Society, Seattle, May 23, 1930.

¹ From the orthopedic clinic of the Children's Orthopedic Hospital.

detritus, suggesting that resorption was in progress. In this case there were no evidences of suppuration. It was his belief that these foci in the bone marrow caused the bone pains which often accompany cases of smallpox.

Mallory,² in 1894, reported the autopsy observations in three cases of smallpox in which the patients died during the stage of suppuration. His descriptions of the foci found in the bone marrow are quite similar to those given by Chiari.

LITERATURE ON REPORTS OF CLINICAL MANIFESTATIONS

In 1903, Debeyre³ observed that cases of osteomyelitis complicating smallpox rarely ended in suppuration.

In 1910 and 1913, Musgrave and Sison⁴ reported a series of eighteen cases of deformities in adults from

another case which showed involvement of the tibia, fibula and ankle joint.

In 1923, W. L. and C. P. Brown⁷ reported two cases, one showing deformities of the forearms and wrists, these having developed following an attack of smallpox three years previously. The roentgenograms indicated destruction of the lower epiphyseal lines of the radius and ulna, and the upper epiphyseal lines in the radius on the right side. The left tibia and fibula also showed evidences of necrotic areas in their distal portions. The right clavicle was shorter than the left. There were no evidences nor history that suppuration or draining sinuses had been present excepting the necrotic area in the tibia. The second case presented a shortening of the right forearm and an overgrowth of the ulna as compared to the radius, causing a radial club hand. There were no evidences of scars, showing that there might have been suppuration. Their report gives an excellent summary of all the literature up to that date.

Fig 1 (case 1)—Elongation of the ulna on the right side

Fig 2 (case 1)—Front view, showing in crease of carrying angle

whom histories were obtained of having had smallpox in childhood and in whom the deformities developed after the attack of variola. The roentgenograms showed extensive destruction in the epiphyseal ends of the long bones. None of these cases showed evidences of former suppurative processes having been present. These cases were all in Filipinos.

In 1912 Cange⁵ reported three cases of deformities of the forearms and hands following smallpox.

In 1922 Sheldon⁶ reported one case showing marked deformities of the elbow and forearm, and

Fig 3 (case 1)—A right wrist closure of the epiphyseal line of the radius elongation of the ulna B left wrist normal

In 1926 Huenekens and Rigler⁸ gave a description of the clinical manifestations of osteomyelitis variolosa.

in its acute stages. They report a case in a boy, aged 6 years, who, some days after the diagnosis of smallpox had been made, developed tender and fusiform swellings of many of the joints in the body, especially those of the extremities. The roentgenograms showed a roughening of the diaphyseal side of the epiphyses as

Fig 4 (case 1)—A right wrist deformity of the distal portion of the radius, B left wrist normal

well as roughening of the epiphyseal side of the diaphyses. There never developed evidences of suppuration, and in due course of time the swelling and tenderness subsided. It would be of interest to have a

Fig 5 (case 2)—A right femur tibia normal B left femur tibia partial closure of the distal epiphyseal line of the femur deformity of the diaphyseal portion of the femur adjacent to the epiphysis

further report from these authors as to the further progress of the case.

In 1929, Lombard⁹ reported two cases of deformities following smallpox, one case showing deformities

of the elbows and numerous scars showing that suppuration had been present. Therefore, this case should be regarded as an ordinary type of acute osteomyelitis. The second case was in a boy, aged 13 years, who had had smallpox at the age of 2 years. There was deformity of the left forearm due to destruction of the lower and upper ends of the radius. There were also destructive bone lesions of the left knee and ankle. From his description there were evidently no evidences of suppuration having been present. He regarded these as being attenuated forms of osteomyelitis which localized themselves in the junta-epiphyseal regions, and that the radius is the bone of preference.

CLINICAL MANIFESTATIONS

From the literature cited it is evident that often the diagnosis of osteomyelitis variolosa is not made during the acute stages of the disease. The patients with smallpox who develop the bone complications do not show deformities until after the attack of smallpox. It is obvious that these deformities would not occur in adults who have had smallpox during adult life, because

Fig 6 (case 3)—A left femur deformity thickening of the distal portion closure of the epiphyseal line B right femur, normal

bone growth has occurred and the virus of the smallpox apparently affects only the epiphyseal lines of the bone. Adults would for that reason not develop these deformities. Therefore, the deformities will occur if variola has been present during childhood or before the closure of the epiphyseal lines has occurred.

The individual consulting the physician does so because of deformity which is present or which may be becoming progressively more marked. In none of the cases that we have seen were there complaints of pain, except because of static disturbances.

REPORT OF CASES

CASE 1—G. B. a girl aged 11 years was brought in because of deformity of the right wrist. There was no history of any previous injury. There was a definite history that she had had an attack of smallpox three years previous to the time of examination. The deformity of the right hand and elbow began to develop shortly after the attack of smallpox. Examination showed the ulna to be markedly elongated as regards the radius and produced a typical radial club hand. The right elbow also showed a markedly increased carrying angle due to the elongation of the ulna (figs 1 and 2). The roentgenograms showed an old destructive process in the

⁹ Lombard, P. Osteomyelitis After Smallpox. *Revue d'orthop.* 16: 490 (Nov.) 1929.

distal end of the right radius with considerable deformity in the region of the epiphyseal line, and apparently almost a complete closure of the epiphyseal line. Other long bones in the body were not affected (figs 3 and 4).

CASE 2—E L, a boy, aged 7 years, was brought in by his mother because she had noticed that the boy had been developing a lump about two years previously which was progressively becoming worse. There was no history of injury or anterior poliomyelitis. There was a definite history of a mild attack of smallpox at the age of 2 years. Examination

Fig 7 (case 3)—A left femur closure of the epiphyseal line and area of decreased density in the distal portion B right femur normal

was entirely negative excepting that there was $1\frac{1}{2}$ inches of shortening of the left lower extremity, this shortening being entirely confined to the femur. Roentgenograms of the left femur showed a partial closure of the distal epiphyseal line and a flaring out of the epiphyseal part of the diaphysis (fig 5).

CASE 3—G S, a boy, aged 14 was admitted to the hospital for treatment of flexion contractures of both hips following a severe tuberculosis of the spine. After his discharge from the hospital he was seen at frequent intervals in the outpatient department. It was noted that he was developing a progressive shortening of the left lower extremity. At 17, this shortening amounted to $2\frac{3}{4}$ inches and was entirely confined to the femur. Roentgenograms showed a complete closure of the distal epiphyseal line of the left femur and a considerable deformity of the epiphysis. There was also a light area a few centimeters above the epiphyseal line indicative that undoubtedly there had been a focus in that location (figs 6 and 7).

A definite history of smallpox in childhood was obtained, and the boy also showed the scars of smallpox on his face.

The fact that this patient had a tuberculosis of the spine might throw some doubt on the correctness of the diagnosis. However it would be extremely rare for a tuberculous process to show the radiologic signs present in this case. Furthermore the definite history of smallpox and the characteristic manifestations would make us believe that we are justified in classifying this as a case of osteomyelitis variolosa.

CONCLUSIONS

1 The virus of smallpox undoubtedly causes a non-suppurative osteomyelitis.

2 The site of election of the virus apparently is in the epiphyseal lines of the long bones.

3 The effect of the virus is to produce an aseptic necrosis which apparently chiefly affects the growing cartilage cells of the epiphyseal lines and causes premature closures.

4 Deformities are caused by the inequality of growth of the long bones.

5 In obscure deformities a careful history of variola in childhood should be obtained.

URETERAL ANOMALIES

REPORT OF A CASE MANIFESTING THREE URETERS ON ONE SIDE WITH ONE ENDING BLINDLY IN AN APLASTIC KIDNEY AND A BIFID PELVIS WITH A SINGLE URETER ON THE OTHER SIDE*

FREDERICK T LAU, MD

AND

ROY B HENLINE, MD

NEW YORK

Recognition of anomalies of the ureter has become common with increase in frequency of the cystoscopic and roentgenographic study of patients. The precision with which the entire urogenital system may be brought before one's eyes has clarified many otherwise obscure pathologic conditions. The advent of iopax (sodium 2-oxo-5-iodo-pyridine-N-acetate, introduced as 'Uroselectan') as an additional means of studying the func-

Fig 1—Diagram based on the models of Keibel and Felix attempting to show the probable development of three ureters on one side with separate renal pelvis. 1 normal ureteral bud branching from the Wolffian duct. 2 hypothetical development of a bifid pelvis or a bifid ureter. 3 hypothetical development of three ureters on one side. 4 a later stage with the three ureters traveling toward the bladder. 5 ureters in the bladder wall, the ureters have separate orifices in the bladder and the Wolffian duct (vas deferens) has completely separated from them.

tion as well as the contour of the urinary tract is another distinct step forward.

* From the James Buchanan Brady Foundation for Urology of the New York Hospital.

Read before the Section on Urology at the Eighty First Annual Session of the American Medical Association, Detroit, June 27, 1930.

LITERATURE

Before it was possible to study the urinary tract completely, the only reference to ureteral anomalies was made from postmortem examinations. In searching the literature carefully we have been able to find reference to only seven cases that were supposed to present three or more ureters on one side, and in each of these there

Fig. 2—Cystoscopic appearance of the ureteral orifices on the right side and the single ureteral orifice on the left side

seems to be insufficient data to give complete proof of their existence.

In 1675, Molinetti¹ mentioned a case of multiple ureters. Copies of his book are so rare that it was necessary to obtain the information from the Medical Library of the Surgeon General's Office in Washington, D. C. Because of this difficulty, we believe it worth while to publish the original reference.

Quinque ego in muliebri cadavere vesicas olim reperi, ac publice ostendi, quibus par renum numerus respondit, sex autem prostabant ureteres, quorum unum minor quolibet vesica excipiebat, duo vero, ut adsolet in maiorem demergebantur in quam per singulares tubulos urina a minoribus destillabat, & consueta via exercebatur.

Translated it would read

I once found five bladders in the cadaver of a woman, the number of kidneys was the same, but six ureters projected, a small one was joined with the bladder, two indeed as is customary, were submerged in a larger one [emptied into a larger one] in which by means of separate tubes, urine trickled down from the smaller ones and was discharged in the usual way.

There were no drawings or further comments concerning this case. Apparently this specimen was one of multiple diverticula of the bladder and an incomplete triplication of the ureters of each side, probably with four ureteral openings in the bladder.

Chopart² in 1830 cited a case of Saloman Albert in which he states that he found three ureters from the right kidney and one from the left "Saloman Albert a trois ureters au rein droit d'un homme et un seul a celui du cote gauche." This amount of data is rather inconclusive.

Gould reported two cases of complete bilateral duplication of the ureters in 1903. The second case showed an ovarian vein which emptied abnormally into the right renal vein instead of into the vena cava. The drawings of this case made this ovarian vein appear to be a third ureter, although Gould did not describe a third ureter on either side. This drawing was reproduced in Watson and Cunningham's⁴ textbook and referred to as showing three ureters on the right and two on the left side. Personal communications⁵ have failed to explain this discrepancy. Papin⁶ doubts whether a case has ever been presented which actually manifests three ureters on one side extending into the bladder with distinct ureteral orifices.

Cunningham states that he distinctly remembers an autopsy on a woman in whom there were three ureters and three kidneys on each side. Further information concerning this case could not be obtained.

Furstner⁷ presents a sketch of a kidney from an autopsy specimen which shows five ureters leading from

Fig. 3—Flat roentgenogram with lead catheters extending to upper and lower halves of double right kidney and third catheter passing to body of sacrum.

the right kidney. These ureters soon fuse in their descent toward the bladder, then divide into two ureters,

¹ Molinetti Antonius. *Dissertationes anatomicae et pathologicae de sensibus et eorum organis*. Padua 1669 p. 303.

and finally fuse again before they enter the bladder in a single ureteral orifice.

Pavaloff⁸ states that Wrangy⁹ described a case presenting three ureters from one kidney, but the triplication was incomplete. He also refers to a case of Forster in which there were supposed to be four ureters present on the right side. Niemeyer¹⁰ presented a case show-

Fig 4—Pyelogram and ureterogram of double right kidney, larger and slightly lower in position than normal.

ing four branches of the left ureter in a child in which many other malformations were present.

One can readily see how uncommon a report of three ureters is in the literature. There is room for doubt whether any of these cases actually manifested three ureters and three ureteral orifices in the bladder on one side.

It is not difficult to understand why anomalies in the urogenital system are so uncommon if one considers its complicated development. The derivation from both mesoderm and entoderm, passing through the stages of pronephros, mesonephros and metanephros, the migration of the kidney from the pelvis to the lumbar region with its rotation around its longitudinal axis, and the complexity of the development of the renal vascular system with its various transformations, permits one to conceive of the possibilities of abnormal development. Patients may go through life without the knowledge that a ureteral anomaly is present unless some pathologic process intervenes. However, pathologic conditions are more prone to develop when an anomaly already exists.

EMBRYOLOGY

To understand thoroughly how double or triple ureters may be formed, one must begin with the earliest development of the ureter. The metanephros, or permanent kidney, first makes its appearance about the fourth week of embryonic life, as a mass of mesodermal cells arising from the caudal portion of the nephrogenic cord. At this time the ureter and entire efferent apparatus makes its appearance as a budding or evagination from the ampullary end of the Wolffian duct close to its point of opening into the cloaca. This ureteral bud grows first dorsally and then turns upward or cranially toward the nephrogenic cells. The end of this bud becomes dilated, forming a cap, which is the beginning of the renal pelvis.¹¹

By a process of dilatation, the lower portion of the Wolffian duct enlarges and becomes continuous with the adjoining portion of the cloaca. The ureteral bud is thus pulled down and incorporated into the dilated portion of the cloaca, which later becomes the bladder. Thus the two ducts acquire separate openings, the ureteral bud emptying into the cloaca (future trigonum vesicae), while the Wolffian duct, destined to become the vas deferens, finds its termination farther down into the prostatic urethra.

Fig 5—Attempted pyelogram on right side of third aplastic ectopic kidney with lead catheters in place to double kidney above.

During this process the cap at the blind end of the ureteral bud divides into two large branches, a cephalic and a caudal branch, and two or more central smaller evaginations which form the adult calices and straight tubules of the kidney. This particular step constitutes an important factor in the formation of ureteral anomalies.

11 Kirwan, T. I. The Role of the Ureter in the Case of the Genito-Urinary Tract. Am. J. Surg. 4, 322-384 (April) 1902.

If the splitting into branches of the blind end of the ureteral bud is slightly premature or exaggerated and this condition persists, the result will be a cleft or bifid pelvis. If the branches of the ureteral bud begin at a point more caudal or nearer the junction of the ureteral bud with the wolffian duct, a partial or complete

Fig. 6—Same as figure 5, with two catheters withdrawn from double kidney

double ureter results, depending on the proximity to the wolffian duct at which the splitting into these branches takes place. Thus the only difference between a diverticulum of the ureter, bifid pelvis, split or Y shaped ureter, fused ureter, and a complete double ureter is one of degree and is dependent on the location of the division into branches at the cap of the ureteral bud.

Felix¹² states that in lower animals two or more ureteral buds are given off separately from each wolffian duct. In the human embryo, however, only the most caudal one normally develops into a ureter. He believes that a double ureter results from two ureteral buds originating separately from the wolffian duct and developing independently. This theory will not explain the more common phenomena of bifid pelvis, split or Y shaped ureter, or diverticulum of the ureter. Since these can all be explained by the previous embryologic sequence, we are inclined to explain our case in that manner.

REPORT OF CASE

M. W., a Negro woman, aged 52, complained chiefly of pain in the right lumbar region extending down into the right leg. The condition was of five months' duration. There was a frequency of urination up to fifteen times a day—none at night—of two weeks' duration. The patient had had dysuria for three or four years. Her family and past history were irrelevant. She had been married twenty years but had no children; the menopause occurred in 1924.

For the past three or four years the patient had had burning urination which had become worse of late. Five months before examination she was ill in bed with bronchitis and since then had had pain in the right lumbar region, which extended into her right leg. The pain had been very severe for the past two weeks and was accompanied by frequency of urination and difficulty in holding the urine. Attempts to hold the urine caused nausea.

A stricture of the urethra necessitated dilation before a cystoscope would pass. The bladder mucosa showed moderate inflammation and bullous edema in the trigonum.

For the purpose of elucidation the ureters on the right side will be described as 1, 2 and 3, 1 being the lowermost on the interureteral ridge, 2 being the middle orifice on the outside of the interureteral ridge, less than 1 cm. above 1, and 3 being above and median to 2 and median to the interureteral ridge. The relative location of these orifices obviously varied with the degree of bladder distention during observation.

A number 6 catheter passed without obstruction to the kidney through ureter 1. In catheterizing ureter 2, a number 6 catheter met obstruction one third of the way up the ureter. After a number 5 bougie had been passed to the kidney a number 5 catheter passed to the kidney through this ureter. In catheterization of ureter 3, a number 6 catheter passed 11 cm. following preliminary dilation of this ureter.

Sterile specimens were collected from ureters 1 and 2 for culture. From ureter 3 several drops of fluid, believed to be reflux from the bladder rather than urine, were obtained. Specimens were also collected from ureters 1 and 2 for urea

Fig. 7—Pyelogram of left kidney showing bifid type of pelvis with slight amount of shaginess of calices.

and microscopic examination. One cubic centimeter of phenolsulphonphthalein intravenously appeared from ureter 1 in three minutes from ureter 2 in two and a half minutes. No dye was obtained from ureter 3. Cultures of urine from ureters 1 and 2 were negative. A number 6 catheter passed to the left kidney pelvis without obstruction; the observations were negative and function was normal.

Roentgenograms were taken before and after injection of sodium iodide solution through each of the three lead catheters.

¹² Felix, Die Entwicklung des Urogenitalsystems in Keibel und Mall, Handbuch der Entwicklungs-Geschichte 1911 p. 2.

The sodium iodide solution did not pass to the kidney pelvis through the third catheter but returned to the bladder. A pyelogram and a ureterogram were subsequently made on the left side.

First roentgenograms were subsequently made also in ten minutes, twenty minutes, thirty minutes, one hour and six hours after the intravenous injection of iopax.

Fig 8—Roentgenogram taken twenty minutes after the intravenous injection of iopax showing the bifid pelvis of the left kidney and the upper third of the left ureter more distinctly than the double kidney on the right side. No evidence of third kidney in this picture. (No shadow is cast with this substance if kidney function is absent.)

COMMENT

The case here presented can be explained embryologically (fig 1) according to the splitting of the single ureteral bud. A pyelogram of the left kidney reveals a

bifid or split pelvis. This is probably the result of the persistence of the primary branching of the ureteral bud which has remained in its embryologic form. In other words, instead of these primary branches joining to form a single normal renal pelvis, they have remained

separate in their most distal portion. This is the simplest and most common malformation.

On the right side, the other extreme occurs. The ureteral bud branched prematurely very close to its origin from the wolffian duct into three main branches, or two main branches and a third sprout from the renal bud.¹³ The lower portion of the wolffian duct, to which the ureteral bud is attached, gradually becomes dilated and forms a portion of the cloaca which is destined to become the bladder. Thus the ureteral bud or ureter is pulled down until it empties into the cloaca. Since the branching of the ureteral bud was very close to the wolffian duct, only a slight further dilatation and growth is necessary to have three separate openings into the future bladder.

Apparently only two of the ureters are connected with kidney tissue. The third ureter seems to end blindly or pass to a possible aplastic, ectopic kidney about the level of the crest of the ilium. There appears to be a "proliferative stimulus" which causes the branches of the ureteral bud to follow the nephrogenic cells upward to form the kidney. It is possible that this stimulus was lacking with the third ureteral bud, either because of insufficient nephrogenic cells or because of the distance between this third ureter and the metanephros.

Fig 9—Same as figure 8 taken thirty minutes after injection of the substance. Other roentgenograms made with iopax did not cast sufficient shadow to warrant including them in this series.

Clinically, the patient has had no discomfort nor symptoms since the routine dilation of the ureters and lavage of the kidney pelvis.

OBSTRUCTION OF THE POSTERIOR URETHRAL VALVE IN INFANCY AND CHILDHOOD

A STUDY OF EIGHTEEN CASES *

MEREDITH F. CAMPBELL, M.D.

Attending Urologist Babies Hospital and New York Nursery and Child's Hospital Adjunct Urological Surgeon Bellevue Hospital

NEW YORK

Urethral valves are the commonest congenital infra-vesical obstruction and, because they are confined to the prostatic canal, render the condition a male disease. Morphologically these valves may be mucosal ridges, folds, cusps or diaphragms. They are most often attached to the verumontanum and, when so involved, this organ is usually otherwise anomalous. When by location or size, valves produce symptoms, the primary

Fig. 1 (case 18).—Greatly enlarged, elongated and anteriorly bifurcated verumontanum in child who died at birth of tentorial tears. Secondary back-pressure, bladder hypertrophy, bilateral ureter dilatation and hydronephrosis are well shown and are especially noteworthy because they developed in utero. In this case the obstructing valves are formed by the anterior bifurcation of the verumontanum.

clinical manifestations are those of obstruction, secondary symptoms are those of uremia. The correct diagnosis is easily made by cysto-urethroscopy. Removal of the obstruction constitutes the treatment. The prognosis is directly proportional to the renal function. A study of eighteen cases of congenital posterior urethral valve obstruction is herewith presented, that all of these patients were children lends particular interest to this lesion.¹

* Read before the Section on Urology at the Eighty First Annual Session of the American Medical Association, Detroit, June 27, 1930.

* From the Department of Urology, Pathology and the Children's Medical Division, Bellevue Hospital, Babies Hospital and New York Nursery and Child's Hospital.

¹ One of these cases (from Bellevue Hospital) was reported previously by Lowsley (footnote 6).

Although Langenbeck² is generally accredited with the original description 128 years ago (1802), Young³ in 1913 was the first surgically to treat the disease. It is noteworthy that of the total of 71 cases reported in the literature to date, only 22 antedated Young's work, these were autopsy observations. Operations were performed in 27 of the 49 reported since Young's original case. With the wider application of urologic methods of diagnosis in juvenile patients with obstructive symptoms or persistent urinary infection, a far higher incidence of urethral valve obstruction will be revealed and, with proper treatment (and such simple treatment), many lives will be saved. Parenthetically it should be added that while valve obstruction will not always be found when indications for complete urologic examination are present, any one of a number of serious or potentially fatal lesions of the urinary tract may be revealed. A liberal attitude toward complete urologic examination in children, particularly when chronic pyuria exists, cannot be overemphasized.

Our present meager statistical data on the incidence of valvular obstruction precludes any estimation of the true ratio of occurrence.

ANATOMY

Structurally, valves may be present only as low ridges, these do not obstruct. More often valves appear as mucosal folds or redundances and in retarding a fluid stream may be cystoscopically observed to balloon into cusp formation. Finally, they may be present as partial or complete diaphragms. In only rare instances, however, have unperforated complete diaphragms been found at autopsy, such a condition is, of course, incompatible with life. On the other hand, the urethral perforation in the diaphragm may be minute, the diameter of a pin, and so cause almost complete obstruction. For convenience, valves have been classified into three types depending on their relation to the verumontanum.

Most valves are contiguous with the verumontanum at some point and usually pass from the anterior end of the verumontanum to the lateral urethral walls (type 1, fig. 1) although in several instances extension from the posterior verumontanum to the bladder outlet has been observed (type 2, fig. 2). Valve segments of the latter type in particular are apt to be multiple, one sometimes finds as many as six or seven folds extending from the verumontanum posteriorly to the bladder outlet. Valves may be unilateral, as I have twice observed, these cause little obstruction. Finally, the valve may be totally independent of the verumontanum, situated either anterior or posterior to this organ (type 3). Such valves are partial or complete diaphragms, occasionally occur on the roof but usually on the urethral floor and, when distended, may simulate a cardiac cusp.

In the presence of valves, the verumontanum is usually anomalous, enlargement and great elongation is the rule. Sometimes the verumontanum extends from the vesical outlet anteriorly for 2 or 3 cm (fig. 1). When the verumontanum bifurcates anteriorly to create type 1 valves, a deep pouch or pocket is often formed at the apex of the fork and because urethral instruments persistently catch in this fossa, passage to the bladder may be exceedingly difficult or even impossible. Such a finding on urethral instrumentation is diagnostically suggestive.

ETIOLOGY

The etiology of urethral valves is unknown. Theorists in this field have believed them to be due to (1) enlargement or hypertrophy of normal urethral folds,⁴ (2) persistence of the urogenital membrane,⁵ (3) anomalous wolffian or mullerian duct developments,⁶

Fig 2 (case 14) — Enormous dilatation of entire urinary tract behind valvular obstruction. The patient was 11 months of age. Destruction of the renal parenchyma by urinary backpressure compression is noteworthy, as is the hemorrhagic decompression cystitis resulting from too rapid emptying of a chronically distended bladder. The morphology of the valvular obstruction merits especial attention. The verumontanum is greatly enlarged, it bifurcates anteriorly to form type 1 valves and extending posteriorly are several deep leaflets forming type 2 valves. The trigon as well as the bladder wall showed marked hypertrophy.

(4) a fusion of the colliculus with the epithelium of the posterior urethral roof. None of these explanations fit all cases.

PATHOLOGY

The pathologic changes in the urinary tract are those common to all infravesical obstructions. A comprehensive understanding of these changes renders simple the correct interpretation of the clinical symptoms and observations, and indicates the requisites of intelligent treatment. The proximal urethra is dilated. Until prolonged backpressure causes muscular decompensation, the bladder wall shows trabeculation, hypertrophy and sometimes inflammation, and may be the site of diverticulum formation. Often trigonal hypertrophy is pronounced. With decompensation, the bladder becomes a large hypotonic bag. Ureteral and pelvic dilatation occur as the disease advances, urinary backpressure as well as inflammatory changes destroy the ureterovesical valve, so that vesicoureteral reflux is demonstrable in

most advanced cases (fig 3). The ureters may become larger than the colon, the renal parenchyma is frequently compressed to a thin shell. Compression nephritis plus infection accounts for the diminution of renal function so uniformly observed as the disease progresses. It is for this reason that prognostic and therapeutic considerations must be translated into terms of renal function.

SYMPTOMS

The symptoms of urethral valve obstruction are (1) those of urethral blockage and (2) those of renal insufficiency or uremia. Since the history must be obtained from a parent in most instances, elicitation and evaluation of the objective symptomatology is often difficult.

Urinary frequency is the most common symptom and is usually present from birth. With the advent of infection, the child may void every twenty to thirty minutes. In many instances a paradoxical or overflow incontinence may keep the child continually wet. These patients in particular are apt to be diagnosed as and treated for enuresis. I have operated in five such cases.

Dysuria or urinary difficulty is due to the diminished urethral caliber and is often distressing. Hesitancy or sluggishness in starting the stream, together with a dribbling flow, are corollaries of dysuria. The observation of the urinary act in one of these little patients with face purple from straining, evincing considerable pain and often manually compressing the abdomen to force out urine, leaves an indelible impression. One of my patients, a boy of 5 years, learned to compress his

Fig 3 (case 7) — Cystographic demonstration of enlarged bladder, dilated ureter and renal pelvis. The upper urinary tract is filled by sodium iodide reflux from the bladder.

bladder over the seat of a chair in much the same manner as an asthmatic patient obtains thoracic compression over the back of a chair. Dysuria may not appear, however, until some months or years after the onset of frequency. In some instances the distressing symptoms of valvular obstruction do not appear until adult life.

*meters creatinine expressed in mg. per hundred cubic centimeters

Chronic distention of the bladder is often visually manifest by a protuberance of the lower part of the abdomen, frequently the mother or the patient has palpated the vesical mass. Such distention usually causes lower abdominal pain, which is often mentioned as an outstanding symptom. With ureteral and pelvic urinary distention, lateral abdominal or loin pain is sometimes present and in conjunction with frequency, dysuria and pyuria commonly leads to the diagnosis of pyelitis. Renal pain on voiding always suggests ureteral reflux.

Later, as renal damage and functional diminution become manifest, the symptoms are those of uremia in progressive stages. Headache, irritability or languor may be the only neurologic symptoms. Repeated and often severe gastro-intestinal disturbances with anorexia, nausea, vomiting, failure to gain or even loss of weight may totally misdirect attention to the alimentary tract. In the terminal stage, the patient either lapses into fatal uremic coma or dies of an intercurrent infection. Debilitated, these patients are particularly prone to acute respiratory or urinary infections, such infections are usually fatal. Because of the clinical picture and laboratory observations, obstruction of the urethral valve is most often diagnosed as chronic pyelitis, chronic interstitial nephritis or polycystic renal disease.

DIAGNOSIS

The history and physical observations suggest the diagnosis, cysto-urethroscopy confirms it. A partially or completely distended bladder is commonly found. The kidneys are often enlarged and, as I have seen, both ureters palpable. A dry tongue is not the rule until uremia is well developed.

Laboratory examination shows urinary infection in most instances. In advanced disease the urinalysis most often leads to the diagnosis of chronic interstitial nephritis, and a high blood nitrogen retention, diminished blood carbon dioxide combining power and reduced output of phenolsulphonphthalein are usually interpreted as diagnostically confirmatory of nephritis. On the other hand, in four of my cases examined because of dysuria and "enuresis," urinary infection and advanced urinary tract changes had not occurred, urinalysis and chemical examination of the blood were essentially normal.

The correct diagnosis is made by cysto-urethroscopy, cystography often gives considerable additional information and should precede cystoscopy. When the bladder residuum is estimated to be more than 3 ounces (90 cc.), gradual decompression should be instituted. In the diagnosis and treatment of urethral valve obstruction, the same basic principles applied to adult

prostatic patients must be even more assiduously observed in children. Decompression and continuous drainage of the bladder usually can be carried out with a number 6 or 7 F ureteral catheter indwelling in the urethra. When the condition of the patient permits, as indicated by the various clinical and laboratory manifestations of improvement, a cystogram should be made.

With 5 per cent sterile sodium iodide the bladder is filled to the point of moderate distention and roentgenographic exposures (preferably stereoscopic) are made. The resultant picture usually shows a distended bladder with irregular wall outlines, sometimes diverticula and by reflux up one or both ureters, the upper tract may be delineated (fig 3). Hydro-ureter and hydronephrosis are commonly found. Ureteral elongation results from urinary backpressure and is roentgenographically evident by kinking, angulation, torsion or sagging of the ureter. The vesical outlet merits special attention because with valve obstruction a funnel shaped shadow extending downward for a centimeter or more is frequently seen. This is due to dilatation of the bladder neck and posterior urethra (fig 4).

With the cystographic data in hand, one proceeds to cystoscopy. Following dilation of the urethra by the passage of steel sounds, passage of the infant cysto-urethroscope is usually easy. On the other hand, instrument tips frequently catch in valve pockets and make instrumentation extremely difficult or impossible. If a diaphragm obstruction with only a small aperture is present, considerable precystoscopic instrumental dilation may be required.

After the cystoscope has been passed, the bladder picture is noted. In one of my cases, the instrument could be passed well into the ureters. Examination of the posterior urethra is usually easy because of obstructive dilatation. This permits an excellent view of the verumontanum and valves

and, by manipulation of the irrigating current, most valves can be made to balloon out. Cystographic and cystoscopic observations render ureteral catheterization and divided renal function tests unnecessary.

DIFFERENTIAL DIAGNOSIS

Valvular obstructions can easily be differentiated from chronic interstitial nephritis and polycystic disease by urologic examination. Other conditions to be ruled out by cysto-urethroscopy are congenital submucous fibrosis of the vesical outlet (so-called contracture²), neuromuscular disease (cord bladder) or hypertrophy of the verumontanum unassociated with valve formation. While all of these lesions may symptomatically

Fig 4 (case 14)—Cystogram illustrating practically all of the characteristic backpressure urinary tract changes that may result from valvular obstruction. The posterior urethra is greatly dilated behind the obstruction the bladder is dilated and irregular both ureters are greatly enlarged elongated and tortuous and finally—although it does not show distinctly—there is marked hydronephrosis. This patient is 11 months of age and still had uninfected urine a finding quite different than one would expect.

simulate valve obstruction, the identification of valve blockage is easy

TREATMENT

Removal of the obstruction constitutes the treatment but as previously indicated this should not be attempted until the condition of the patient warrants surgical attack. If the residuum is over 3 ounces, gradual decompression and continuous bladder drainage should be carried out until functional stability has been established. If the residuum is less than 3 ounces, preliminary drainage for a few days is excellent practice. With continuous drainage, the blood on chemical examination, the phenolsulphonphthalein output and the general physical condition of the patient will in the course of a few days or weeks attain a degree of improvement which further drainage does not augment. Operation may then be carried out. If the patient does not tolerate the indwelling urethral catheter, cystotomy decompression and continuous drainage must be resorted to. My experience with indwelling urethral catheter drainage in older boys has paralleled that in adults, but in very young boys maintenance of this form of drainage may be exceedingly difficult. During the preliminary drainage period, water in abundance and rest is the best treatment, urinary antiseptics are not needed.

Several methods of valve removal have been advocated. Perineal approach is unsatisfactory and unnecessary. If the urethra is impassable or cystotomy drainage has already been instituted, a suprapubic attack may be carried out. Young has satisfactorily removed valves with his miniature punch, others⁹ have destroyed valves by fulguration and in some instances the valves have been ruptured by the passage of steel sounds. I have successfully used the electrotome cutting current with which, under visual guidance, one can excise the obstructing valve leaflets. At the same time the size of the verumontanum can be reduced if it is abnormally large. Reference to the accompanying tabulation of our cases indicates that this method gives thoroughly satisfactory results. There is a minimum of surgical shock, in young boys the procedure is carried out under gas anesthesia and, in our experience to date, postoperative bleeding or other undesirable sequelae have been negligible. On the other hand, we have been fortunate in getting our operative cases relatively early.

Fluid in abundance is the best medicine following operation. If the obstruction has been properly removed, urination will be free. The administration of urinary antiseptics at this time is unnecessary. Anemic children or those in whom the need of transfusion seems at all likely are best given the blood before operation.

PROGNOSIS

The prognosis is based on the degree and duration of the obstruction and is directly proportional to the renal function and damage. Fortunately the low renal function of compression nephritis is not always as ominous as the initial observation might suggest for, with continuous preliminary drainage renal function not infrequently returns to a satisfactory degree. Therefore a somewhat more accurate prognosis can be rendered after one has observed the quantitative improvement in renal function following continuous preoperative drainage.

SUMMARY

With more careful attention to urologic symptoms and with wider application of technical urologic diagnostic procedures in children, a far greater incidence of urethral valve obstructions (as well as numerous other forms of serious urinary tract disease) will be found. The valves are congenital, the embryonic mechanism of their formation is unknown. Symptoms are those of infravesical obstruction plus renal damage. The diagnosis is easy to make if one will employ cystography and cysto-urethroscopy. A careful preoperative treatment with gradual bladder decompression and continuous drainage when indicated together with a large fluid intake is imperative for successful surgical results. Removal of the obstructing valves by the cutting current is strongly advocated because (1) it may be carried out under vision, (2) there is a minimum of surgical shock or disturbance of the urinary tract after operation, and (3) thoroughly satisfactory results are obtainable.

33 East Sixth-Eighth Street

SOLITARY SEROUS RENAL CYSTS

WITH A STUDY OF ROENTGEN OBSERVATIONS*

ROBERT HERBST, M.D.

CHICAGO

AND

WILLIAM J. VYNALEK, M.D.

BERWYN, ILL.

Each year brings increasing numbers of case reports of solitary serous renal cysts. In 1920 Kretschmer¹ collected but forty-seven cases reported in the literature, adding one of his own. Only seven years later, Carson² gathered 142 plus 3 of his own, and in the few months that elapsed before his article was published, 6 new cases had cropped up. Today more than 160 cases have been reported, and whenever this condition is discussed, new cases, not reported in the literature, are mentioned by those present. Löffler,³ in introducing four of his cases, writes "Retention cysts of the kidney occur as solitary and multilocular cysts and are frequently found by the pathologist. The clinician observes them less frequently because, in themselves, they produce no pain." Branch,⁴ in a recent article, states that pathologists see these cysts in from 3 to 15 per cent of routine autopsies, and he stresses the fact that he refers only to true solitary serous cysts at least 4 or more centimeters in diameter, and not to small retention cysts. It is likely that with the numerous cases being reported diagnostic acumen may increase so that, as in the case of congenital bilateral polycystic kidneys, which a decade ago were still uncommon enough to warrant reporting or as in the case of diverticulum of the bladder, when in the year 1906 only five cases had been reported in the United States in the near future more cases will be seen and discussed, and the much flaunted idea of rarity will not deter one from venturing a preoperative diagnosis of solitary renal cyst. Though the condition is certainly uncommon clinically it is not as rare as originally believed, even though nearly every article on the subject begins by stressing its rarity.

Some confusion still exists as to the roentgenographic and urographic observations in this condition. George Gilbert Smith,⁵ in 1924, said, "There is relatively little known as to the pyelographic study of these kidneys." Clute⁶ in the same year, said "The appearance of a round swelling arising from one pole of the kidney, separated from or overlying a normal pelvis is the typical pyelogram." Eisendrath⁷ writes "If the cyst does not displace the renal pelvis, and this is true of most of the cases, the pyelogram will not reveal any changes from the normal." Young⁸ states that no solitary cyst has been seen at the Brady Institute and that pyelography should be done, "though we are unable to give any statistics as to its diagnostic value." More recently however, Colston⁹ described a case of solitary cyst and papillary cystadenoma seen at the Brady Institute.

Fig 1—Pyelographic tracings of solitary serous renal cysts. a, b and c, blunting of calices adjacent to cyst (McKim and Smith). d, abbreviation of middle calix (Brasch). e, absence of middle calix, upper only partially filled (Louis Smith). f, cylindrical pelvis, only an upper abbreviated calix remains (Brasch). g, hydronephrosis and displaced ureter (Clute). h, pelvic axis displaced horizontally and pushed upward (Brasch). i, calcified cyst, pelvic dilatation, flattened calices (Kirmm).

Recently we had a case in which the pyelogram was so unlike any we had ever seen that we examined the literature in an effort to draw some simple definite conclusions as to the status of roentgenography and urography in this condition. As early as 1911 Brasch suggested pyelography in the diagnosis of solitary cyst and his first book on urography shows several pyelograms. Schulman,¹⁰ in 1916 reported a case in which

pyelography was done and a diagnosis of hypernephrosis was made. He did not show or describe his roentgen observations. Kretschmer's pyelogram in 1920, was still one of the few on record and showed a hydronephrosis. Since that time pyelography with other refinements of urologic diagnosis has been more extensively utilized. A simple explanation will clear the needless confusion that exists regarding pyelographic changes. Solitary cysts regardless of the disputed theories of origin involve the cortex. Pyelographic observations will depend on the relationship of the cyst wall to the pelvis or its calices to any changes produced in the course or lumen of the ureter by virtue of pressure from a large cyst, and to any change in the position of the kidney from pressure or increased weight. Naturally, those cysts arising in the upper pole or middle of the kidney will be more apt to produce pelvic pressure changes than those arising in the lower pole and growing downward away from the kidney pelvis. The last group is most common and more likely to produce pressure changes on the ureter with resulting pyelectasis.

From those reported we have summarized the more common characteristics of roentgen observations and have had tracings made of pyelograms illustrating the representative groups. These are six in number: (1) normal, (2) hydronephrosis, (3) compression of the calix or the true pelvis, (4) change in position and axis of the kidney, (5) the outline of the cyst and (6) calcification of the cyst wall.

1 The pyelogram may be normal. If the cyst does not impinge on the pelvis there will naturally be no compression of the pyelogram. This of course is true in the great majority of small cysts. We do not believe

common in those large enough to cause clinical symptoms, for pain is almost invariably due to pressure changes and the average diameter of such cysts, according to McKim and Smith,¹¹ is 15 cm. Conversely, the fact that a cyst is small does not necessarily mean that

association with or independent of flattening of the calices there may be similar infringement on some other portion of the renal pelvis. Occasionally this gives rise to a cylindric pelvis. Blunting of calices was seen in all three cases of McKim and Smith and is probably

one of the earliest recognizable pyelographic changes. With more pressure retraction of calices is seen and is one of the most common observations. Flattening of the pelvis without changes in the calices may occur if the cyst arises on the mesial kidney border.

4 A change in the position and axis of the kidney as a result of increased weight on one pole is given by Braasch¹³ as one of the three pyelographic deformities produced (fig 1 h). In his book he stresses (a) abbreviation of adjacent calices (b) compression and flattening of the adjacent portion of the renal pelvis and (c) a change in the position and axis of the kidney.

5 The outline of the shadow of the cyst itself is the roentgenographic observation of greatest importance from the frequency of its occurrence and from its diagnostic value. This has often been discerned distinctly in close relationship to the kidney and frequently displaced ureter.

The relative difference in density of the typically large, rounded shadow to adjacent solid organs suggests its cystic nature and is clearly brought out in cases in which the tumor overlies the kidney,

Fig. 4 (case 3)—Upper pole cyst change in position and axis of kidney and pressure on superior pelvic outline; ureter displaced.

Fig. 5 (case 4)—Cyst involving entire anterior wall of kidney from pole to pole; renal pelvis with all calices obliterated.

the pyelogram will always be normal. Several of the most marked defects have been produced by small cysts growing near and pressing early on the pelvis. Dr. Louis Smith¹² describes a case showing absence of the middle calix and an upper calix only partially filled caused by a cyst 1 by 1.5 by 3 cm. in the upper pole (fig 1 e).

2 Hydronephrosis is the most common deformity due to the frequency of the lower pole cysts (fig 1 g). This is unfortunate in that it undoubtedly obscures early and slight flattening of the renal pelvis so valuable in diagnosing this condition. It is this fact that has undoubtedly given rise to the erroneous idea that the pyelogram is usually normal. A secondary hydronephrosis is usually caused by tumors which displace or obstruct the ureter, interfering with drainage; such cysts are usually large enough to give other diagnostic clues. Even in this type of deformity, we feel that there should often be some direct pressure change on the pelvis or calices, which, even though slight, should be sought and considered in evaluating the various points of information. It would be unfair for us to say that some of the pyelograms shown in the literature as normal or with simple hydronephrosis did show localized pressure changes, as it is impossible to judge these reproduced pyelograms, and for this reason we have had the artist make skeletal tracings of our pyelograms to show changes that would be lost in the reproduction on lantern slides or on the printed page.

3 Compression of the pelvis nearest the cyst is a most suggestive feature in some pyelograms. There may be slight flattening or blunting of the adjacent calix or calices (fig 1 a b c). Abbreviation may be more marked and frequently one or more calices are completely obliterated (fig 1 d e f). One of our cases was unusual in that all calices were absent (fig 5). In

Fig. 6 (case 4)—Relation of cyst to anterior renal wall and bed remaining after partial resection of cyst; kidney was not removed at operation.

allowing the latter to show through quite clearly. We cannot give statistics as to its frequency as the literature

is vague on roentgenographic details but we believe that a careful search will show the larger cysts in most cases. They were seen clearly in all ours and in many cases reported in recent literature. The increasing frequency of this finding in more recent years is probably due to improvements in modern roentgenographic technique.

Fig. 7 (case 4)—Five weeks after partial resection of cyst; note renal ptosis and dilatation of superior calyx; compare with figure 5 before operation.

Fig. 8 (case 5)—Upper pole cyst filled with blood; patches of calcification in wall; upper calyx absent.

6. The shadow produced by calcification of the cyst is an interesting but less common finding. It was seen to best advantage in a case described by Kirwin¹⁴ (fig. 14).

Another diagnostic feature was utilized by Ormond¹⁵ in diagnosing a solitary serous cyst. He was able to show that the slightly dilated renal pelvis moved downward with the palpable abdominal mass, pyelograms being taken before and after applying downward pressure on the tumor with the hand. This fact associated the mass of lesser density with the kidney proper and enabled him to make a correct preoperative diagnosis.

These six features characterize roentgen observations in cases found at operation to be solitary serous renal cysts. Prior to 1923 only seven correct preoperative diagnoses had been made out of ninety-four cases collected by Harpster¹⁶. Of the seven, three were made from plain roentgenograms. Since that time quite a number have been correctly diagnosed, but unfortunately exact figures cannot be given because most reports fail to state whether a preoperative diagnosis had been ventured. However, the diagnosis is even today only too often made at operation. It is to be hoped that, with knowledge gleaned from a discussion of roentgenographic observations, diagnostic skill will increase.

Cases with obliteration or marked retraction of the calices are usually diagnosed, and quite naturally, as neoplasms. This is especially true with small cysts. Solitary cysts are, and present the pyelograms of, kidney tumors. Of importance in ruling out neoplastic

growths is the absence of bleeding. Hematuria has occurred in these cases but usually because of some associated pathologic condition as stone or chronic nephritis. Function is usually normal or only slightly reduced with solitary cyst. On palpation of large cyst a sense of elasticity may be determined. Neoplastic changes frequently cause as the earliest deformity elongation, rather than abbreviation of the calices. As a neoplasm enlarges toward the periphery it stretches the calyx with it so that elongation is accompanied by narrowing. Bizarre distortion may occur as a result. A neoplasm as large as the usual cyst observed clinically is likely to cause extensive pelvic deformity.

Pyelography can never replace a careful history, physical observations, and other urologic data in the diagnosis of cyst. Nor should it be used except as an adjunct to other observations in the diagnosis of any other renal condition. However, with compression seen in the pyelogram kidney involvement should be suspected though it may not be interpreted correctly, and exploration should be considered. If the outline of the cyst is seen near or overlying the kidney a preoperative diagnosis can often be made, especially if there are pyelographic pressure changes.

At operation, resection of a wedge-shaped portion of renal tissue with the cyst is the ideal treatment. The cyst is characteristically attached firmly to the adjoining parenchyma and can seldom be shelled from its bed. Learning dissection is crude at best and more likely to be followed by secondary hemorrhage than the removal of a portion of the kidney with the cyst wall and the bringing together of the resulting V-shaped defect by approximation sutures.

Fig. 9 (case 5)—Blood-filled solitary cyst removed at operation. Kidney and cyst have been laid open by longitudinal incision.

If the growth is large or multiple, and if resection should necessitate too great a loss of renal tissue, the cyst may be cut off flush with the renal border and its base cauterized. Following either of these procedures, the kidney should be sutured in normal position to prevent displacement in the resulting cavity left by the removal of a large cyst. Nephrectomy has been fre-

quently utilized in the past but unless an associated malignant condition is suspected or parenchymatous damage is too great, more conservative surgery is indicated.

We are presenting brief histories of six cases, in five of which a tentative diagnosis of solitary renal cyst was made before operation as a result of roentgenographic data. In one case a diagnosis of renal tumor was made before and at operation, but pathologic study revealed a blood-filled cyst.

REPORT OF CASES

CASE 1—S C, a man, aged 70, was admitted to the Presbyterian Hospital in the service of Dr. Oberhelman, complaining of attacks of pain in the left loin radiating anteriorly to the groin. Symptoms were of only a few days' duration though a year before he had suffered painful attacks on the right side which were described as heavy, pulling sensations. No hematuria was present.

Examination was essentially negative. At cystoscopy we discovered a stone in the left intramural ureter but when roentgenograms were made (fig. 2), in addition to this calculus was seen the shadow of a cyst the size of an orange overlying the lower pole of the left kidney. The pyelogram itself was practically normal though there was a slight blunting of the inferior calyx and some flattening of the inferior pelvic border. The stone passed spontaneously and the cyst was resected at operation.

In this case the pyelogram showed but little abnormality because the cyst was small did not encroach on the pelvis to any extent and occupied the lower pole but the presence of the cyst was clearly seen and permitted of a preoperative diagnosis.

CASE 2—N R, a man aged 58, was admitted to the Presbyterian Hospital complaining of pain in the back over the right kidney for two weeks. Epigastric fullness had been noted for many years. The dull backache was aggravated by sharp exacerbations with radiation of the pain anteriorly. No hematuria had been observed.

Repeated plain roentgenograms with catheters in situ suggested a calculus in the right ureter but it was not until pyelography was utilized that the true pathologic condition was discovered. The roentgenogram (fig. 3) showed a distinct deformity of the right superior calyx, which was somewhat enlarged and curved on its upper part as if by pressure from above. A second film repeated this deformity and showed retention of almost all the solution in the kidney which was pushed down to the third and fourth lumbar spines. A globular shadow the size of an orange lay over the upper pole of the kidney and was apparently causing the pyelographic defect. This shadow was not heeded until the pyelogram was made. Function tests and urinalysis were normal.

A diagnosis of serous renal cyst was confirmed by operation. The pyelographic change was one of blunting of a calyx and it is interesting to compare this pyelogram with that of case 1 in which a cyst of the same size situated at the lower pole caused practically no deformity.

CASE 3—Mrs. R B, Negro, aged 36, was admitted to the Presbyterian Hospital in the service of Dr. Bevan complaining of abdominal swelling, dull backache and bearing down sensations. The symptoms followed the birth of a child, four years before. No hematuria had ever been present. Elsewhere a diagnosis of ovarian cyst had been made two years before.

Examination revealed a cystic mass occupying the entire left half of the abdomen. It moved with respirations and the kidney could not be palpated. Air inflation of the colon indicated a retroperitoneal position of the mass. Pyelography (fig. 4) revealed a distorted kidney pelvis at the level of the fifth lumbar spine overlying the iliac crest. It was elongated as if by compression from above by the large shadow of the cyst which was clearly seen. Urinalysis and function tests were normal.

At operation the large solitary serous cyst was resected from the upper pole and the prolapsed kidney was secured in good position by sutures. The pyelogram falls into the group of

"change in position as a result of pressure and weight" and also shows direct pressure on the superior pelvic outline.

CASE 4—Mrs. A K, aged 53, entered the Berwyn Hospital, complaining of pain in the left side of the abdomen for six years. At times, especially after meals, suffering was intense. It was a sense of heaviness and there were no urinary symptoms whatever.

The essential finding on examination was a large, rounded, firm mass filling the entire left side of the abdomen. It was not tender, and a sense of elasticity was noted. There seemed to be no direct connection with the pelvic organs. Blood and urine were normal.

Plain roentgenograms revealed the large, rounded mass of a tumor, superimposed on which the kidney shadow of normal outline could also be seen quite distinctly in spite of the patient's obesity.

Cystoscopy showed no drainage in forty-five minutes from the left kidney but perfect function on the right. A left pyelogram (fig. 5) revealed a normal sized, oval pelvis with

all calices completely obliterated. The kidney lay in about the center of the larger, rounded, less dense shadow of the cyst, which filled the entire left side of the abdomen. Injection of air showed that the bowel lay anterior to the mass. A tentative diagnosis of renal cyst was made, though the anuria on that side was puzzling. Operation revealed a large solitary serous cyst of the anterior surface of the kidney extending from the superior to the inferior pole practically bisecting the anterior half of the kidney (fig. 6). It measured about 18 cm. in diameter and had burrowed down to the pelvis but was not connected with it. It had dissected its way between the posterior

Fig. 10.—Multiple small cysts of lower pole overlying margins gave an erroneous impression of calcification thinning out of iodine in middle and lower calices (opaque medium here shown in white in contrast to black on other figures).

peritoneal wall and the ureter so that the latter was not displaced laterally. It contained clear, watery fluid. We resected the cyst flush with the kidney surface, cauterized its renal base with phenol and packed this bed. The kidney appeared normal in all other respects and we were reluctant to resect the cyst completely because it meant injuring the large vessels on the anterior renal pelvic wall and opening the pelvis proper as the cyst wall could not be shelled away. Such a formidable procedure might have necessitated a nephrectomy and we wished to observe the recuperative powers of that kidney.

Convalescence was uneventful, the patient leaving the hospital on the thirteenth day after operation. Cystoscopy three weeks later revealed perfect function in both kidneys. A pyelogram at this time (fig. 7) revealed some dilatation of the superior calyx with normal middle and lower calices. In spite of extensive packing about the kidney postoperative ptosis occurred, the pelvis being found opposite the third lumbar spine instead of the first as in the preoperative pictures. The cavity left following removal of the cyst was so large that suture fastening of the kidney in a more ideal anatomic position would have been preferable.

This cyst had obliterated all calices in the pyelogram and was unusual in the location and extent of involvement of the anterior renal surface.

CASE 5—Mrs. R M, aged 61, was admitted to the Presbyterian Hospital in the service of Dr. Abbott complaining of

pain in the left flank of twelve weeks' duration, associated with vomiting and fever. The onset had been sudden following an automobile trip. She had no other symptoms and no hematuria. Physical examination was negative except that the left kidney was more easily palpable than the right. A plain roentgenogram showed enlargement of the upper pole of the right kidney with a suggestion of calcification in this area. The pyelogram showed in absence of the upper calyx (fig. 8). A preoperative diagnosis of kidney tumor was made.

At operation we felt we were dealing with a tumor and removed the kidney. When it was opened a cyst was found containing free blood and material resembling organized clots (fig. 9). Sections revealed this material to consist of necrotic debris, lymphocytes and some fibroblasts. There was no evidence of neoplastic tissue. The wall was hard and leathery.

There is some question as to whether this might not be more appropriately classified with true solitary hemorrhagic cysts which Begg¹ of New Zealand states are in a different category from solitary serous renal cysts. Hemorrhagic cysts usually show pyelographic changes because some portion of the renal pelvis is almost certainly involved. In our case we feel that hemorrhage had taken place into a serous cyst.

The roentgenogram did reveal the tumor but because of its contents, its cystic nature was not suspected. The pyelogram falls into the group of obliterated calices. Early calcification of the cyst wall recalls Krukenberg's case.

CASE 6—C. F., a man aged 60 was admitted to the Presbyterian Hospital complaining of pain in the back of one week's duration. There had also been some difficulty in starting the urinary stream and hematuria had been noticed shortly before admission. There was moderate enlargement of the prostate, which was confirmed at cystoscopy and was probably the cause of hematuria and difficulty in urination.

Roentgenograms revealed a circumscribed area of increased density about 7 cm. in diameter, over the lower pole of the left kidney. The lower margin was so distinct as to suggest calcification. A pyelogram (fig. 10) revealed a partial filling—a thinning out of the iodide—of the middle and lower calices as if by extrinsic pressure. The upper ureter was displaced medially. A diagnosis of cyst of the kidney was made with probable calcification of the wall. The sudden onset of pain suggested the possibility of recent hemorrhage as in the previous case.

At operation four cysts were seen springing from the renal surface. One was attached to the lower pole two to the posterior surface of the kidney, at its middle and one to the convex border. Three of these cysts were as large as a small orange, and one was the size of a crabapple. The walls were thin and there was no calcification. They contained a yellowish clear serous fluid. None of them communicated with the pelvis of the kidney. The cysts were cut off flush with the renal surface, and their bases were cauterized with full strength phenol. They were not resected, because the kidney parenchyma looked normal and resection of four cysts would have been too destructive.

The pyelogram shows compression, but, unlike the blunting in other cases, the picture was one of thinning out or fragmentation. The outline of the cyst showed clearly and the margin suggesting calcification was apparently produced by overlapping of two cysts. The multiplicity of cysts does not alter the diagnosis of solitary serous renal cyst as the literature seems to include this type in the terminology designated

SUMMARY

1 Solitary serous renal cysts, though uncommon clinically, are not so rare but that they warrant consideration and elimination in all tumor masses of the abdomen. With increasing data available from the numerous cases being reported it is probable that a preoperative diagnosis will be made more frequently.

2 The roentgenogram may show (a) a normal pyelogram, (b) pyelectasis, (c) compression of the calices or the true pelvis, (d) change in position and axis of the kidney, (e) the outline of the shadow of the cyst itself, or (f) calcification of the cyst wall.

3 A most important and frequent roentgenographic finding is the outline of the shadow of the cyst itself, in close approximation to the solid renal shadow and with density in marked contrast to that organ. A careful search should always be made for this shadow. It is more likely to be overlooked on a plain film than with the pyelogram.

4 A cyst large enough to cause clinical symptoms is often associated with an abnormal pyelogram, which, though seldom absolutely typical of the cyst, nevertheless calls attention to pathologic changes in the kidney.

5 Resection of a wedge-shaped portion of renal tissue with the cyst is the treatment of choice. This method is less likely to be followed by secondary hemorrhage than the attempt at mere resection of the cyst wall. Rarely can the latter be shelled from its renal bed. The kidney should be fixed in place by sutures to prevent postoperative ptosis in the resulting cavity. Nephrectomy should be carried out only in cases of extreme renal damage or suspected associated cancer.

6 Six cases are reported, five of which were diagnosed correctly, before operation, the sixth a hemorrhagic cyst as a renal tumor, all by virtue of roentgen observations.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRs. LAU AND HENLINE, CAMPBELL, AND HERBST AND VANALEK

Dr. ROBERT E. CAMPBELL, Detroit. My own notion regarding the etiology of solitary serous renal cysts is that such cysts are perhaps acquired disease, not congenital. There is, however, probably an element akin to such congenital deformations as polycystic kidney disease in that there may be a group of cells located in that portion of the kidney in which such cysts develop (having been actuated by infection trauma or other unknown agents) that have the faculty of developing into these solitary cysts. The results of microscopic examination are indeterminate. The lining membrane usually being so much on stretch as to preclude certain knowledge as to whether this lining is of endothelial or epithelial origin. Our conception relative to polycystic disease being always bilateral has been borne out in a number of instances in which one kidney presented grossly only a single or possibly two large cysts. Microscopic examination of the kidney, however, revealed early degenerative changes typical of polycystic disease. I am in accord with the idea expressed recently by Braasch that the so-called hemorrhagic cysts are the same type as described by Drs. Herbst and Vanalek, the bleeding being a secondary factor. The authors' data relative to diagnosis and treatment are most valuable and are worth using in individual work. Concerning the interesting anomaly reported by Drs. Lau and Henline, the condition is well developed embryologically and we are once more cautioned to be on the lookout for such involved conditions, which may account for many difficulties in handling obscure urologic lesions. Drs. Lau and Henline adopted the obviously correct method of treatment in the case reported and were fortunate in having intravenous urography at their disposal as an aid to diagnosis. Relative to Dr. Campbell's method of preliminary conservative treatment and diagnosis I feel that chromocystoscopy by means of indigo carmine is of definite value at the time of cystoscopy serving to give data on differential function, which adds to the accuracy of later therapeutic procedures. I approve heartily of his method of actual treatment of the obstruction and I am sure that no one is better qualified as an authority than Dr. Campbell. I am sure, also, that many of these cases are never discovered and that there are many more which have been discovered and some of them successfully treated, which have not as yet been reported. I myself have seen fourteen cases with obstruction of this nature during the last ten years.

Dr. HERBERT T. HAYES, Houston, Texas. I was especially interested in the paper of Drs. Lau and Henline in their report

of three ureters on the right side. I think they should be complimented on the way they have worked up this case. In a case that came to my attention, there were three ureters on the left side. Two were complete and the third was about 1½ inches long. A pyelogram revealed that the large pelvis was the lowest in the kidney but that the ureteral orifice was the highest on the left ureteral ridge. The second ureteral orifice was slithlike and below the first. The second ureter had a small pelvis in the kidney that was above the larger and more normal pelvis. The third ureteral orifice was slithlike and below the second and closest to the vesicle orifice. This ureter was only about 1½ inches long and ended blindly. When the sodium iodide was injected into it there was considerable pain. This man had infection of only one ureter. The urine from the highest ureter was of amber color, was of high specific gravity, and was not infected. Urine from the second ureter was of low specific gravity, was infected, and there was a slight stricture of this ureter. This was dilated and the kidney pelvis lavaged several times.

DR CHARLES C. HIGGINS, Cleveland. Literature has led to the inference that solitary cysts of the kidney are of rare occurrence. Of 154 cases reported recently, at least, two thirds have been collected during the last five years, indicating that since the urologist has become acquainted with this type of pathologic kidney it is now being recognized more frequently. As a general rule, solitary cysts of the kidney do not produce symptoms unless they attain a size sufficient to exert pressure on the adjacent structures. Individuals may have a cyst of the kidney the size of a lemon and not be aware of its presence. At the Cleveland Clinic we have had nine cases of solitary cysts of the kidneys. Of the nine cases, seven have required surgical intervention. It is interesting that in only two cases were the cysts of such a size that pressure phenomena were notable. A roentgenogram may be normal even with a cyst of moderate size. In two cases of our series the plain roentgenogram showed a large cyst attached to the lower pole of the kidney, and a diagnosis of solitary cyst was made from roentgenologic study. Heminephrectomy is the treatment of choice for this condition and was performed in five of these patients. In two of them there was an associated colon pyonephrosis, and a nephrectomy was indicated. If the patient's condition does not warrant a heminephrectomy, a more conservative treatment can be instituted, namely, marsupializing the cyst wall to the incision similar to the treatment employed in caring for a pancreatic cyst. After the patient's condition is satisfactory, the cyst may be removed by performing a heminephrectomy, however, there is no doubt, as Drs. Herbst and Vynalek have emphasized, that heminephrectomy, if possible, is the treatment of choice for this condition.

PROF. EDMOND PAUL, Paris. The paper of Drs. Lau and Henline is extremely interesting and important. One must consider it as the first case of triple ureter observed in the living patient. I have made many studies of anomalies of the kidneys and ureters and after having thoroughly reviewed the literature I have concluded that up to the present time there has been no authentic case of triple ureter. The old cases are all poorly described, the majority are only trifurcations. Gould's case is false. It is interesting to have a well studied case of true triple ureter and gives rise to the question of the theoretical origin of anomalies. It is easy to understand why this malformation is exceedingly rare. Double ureter is due to premature bifurcation of the ureter into the two major calices. Triple ureter results from early defurcation of one of these ureters. It is therefore an anomaly of an anomaly or if you so wish an anomaly of second degree. All cases should be studied with great care and Drs. Lau and Henline must be thanked for their interesting and complete observations.

DR FREDERICK T. LAU, New York. I believe from the study of our case that it can be explained embryologically according to the splitting of the ureteral body. I think that the case seen by Dr. Hayes is exactly like ours but that the opaque medium did not go up so far. A pathologic point to which I sendraath called attention some years ago is interesting. That is, when one encounters a double ureter, the ureter draining the upper portion of the kidneys always empties into the bladder at a point below the entrance into the bladder of the ureter that drains the lower portion of the double kidney.

PHYSIOLOGIC MEANING OF COMMON CLINICAL SIGNS AND SYMPTOMS IN CARDIOVASCULAR DISEASE*

CARL J. WIGGERS, M.D.

Professor of Physiology, Western Reserve University Medical School
CLEVELAND

Medical diagnosis is a science that involves more than the ability to recognize signs and symptoms and subsequently to group them into complexes or syndromes which in the light of past experience makes it possible to call a disease by name. Even a modest claim to proficiency requires a knowledge of the pathologic anatomy involved. But real genius in diagnosis is not achieved without the mental ability to portray also the functional disturbances concerned.

But all progress in eliciting obscure signs and new evidences of diseases and all discoveries in diversified fields of physiology have operated rather slowly in placing diagnosis on a physiologic basis. There are obvious reasons why the morphologic basis of disease antedated the functional conception. Morphologic pictures are concrete, they make a direct appeal to the senses. Physiologic processes are generally abstract, the mind can group them only through the employment of physical and chemical aids that transform physiologic forms of energy into types that can be interpreted by the senses. Many physiologic properties of living tissue—conduction or metabolism may be taken as examples—are as insusceptible of recognition by human sense organs as are radio, ultraviolet or x-ray vibrations. Nevertheless, by employment of the string galvanometer and cathode ray oscillograph, the mysteries of the conduction process have become comprehensible, and now it is virtually possible to see the excitation process spread over a heart or a nerve, to know where it begins and where it halts, how often and how fast it travels. The methods of direct and indirect calorimetry practically enable the physiologist to watch the vital fire of life burning within the cells, he can fathom the quantity and character of the substances burned as well as the rate of combustion under different circumstances. These instances suffice to recall that the unraveling of nature's intangible mysteries called functions usually requires the employment of complex physical apparatus or involved chemical procedures. To facilitate expression and intercommunication of facts discovered by such methods, new words, terms and phrases are necessarily introduced. Hence, it frequently follows that the mechanism and meaning of functional processes must at first be couched in language that is not universally understood. So it comes about that many a field of interesting scientific discovery remains in the cocoon stage because the abstract ideas involved cannot easily be translated into concepts that the mind easily grasps.

This extremely slow hatching process involved in the birth of new physiologic facts and the equally slow metamorphosis that their modes of expression must undergo are not the only factors that have retarded the functional interpretation of disease. Perhaps equally significant though more easily remedied, is the faulty impression that the functional reactions of disease differ intrinsically from those in health whereas in reality they differ only in degree. A great variety of physiologic processes are continually recurring in the

*Second Beaumont Lecture delivered in Pittsburgh N.Y. at the Philadelphia Hospital Annual Round Table Conference Aug. 23, 1930.

body as a result of chemical and nervous stimuli, but since the reactions are normally balanced, function continues on an even keel, and the mind remains unaware of them.

Physiologists frequently carry out laboratory experiments in which a single reaction or a group of reactions is intensified, depressed or inhibited through the employment of artificial chemical or nerve stimuli. Thus, on an anesthetized animal, one may stimulate an afferent nerve with an electric current and produce a reflex fall of blood pressure. A shop worker who accidentally crushes a finger duplicates the same experiment with the difference that, being conscious at the start, he faints.

Again, the student may perform a respiration experiment by partially occluding the trachea of an anesthetized animal in which case anoxemia and hypercapnia of the blood occur and stimulation of the respiratory center causes deep and rapid breathing. He may himself carry on a similar experiment by taking vigorous exercise. The respiratory reactions are identical with those of the laboratory animal; only the human mind becomes conscious of the dyspneic breathing. By filling the alveolar spaces with liquid and fibrin so that a rapid interchange of oxygen and carbon dioxide is prevented, nature produces the same respiration experiment, and the disease is called pneumonia.

In short, every form of disease may be looked on as an experiment that nature performs on animals or man. The so-called symptoms of disease are nothing more than intensified or depressed reactions which, if not actually in operation, are at least potentially available in the normal organism. No pathologic process in disease is capable of evolving new types of functional reactions. Neither is it capable of exciting or depressing functions that cannot be similarly affected by artificial or natural means in normal organisms. The methods employed by nature in experiments are often cleverly concealed and hence not always fully understood. It is the task of experimental physiology and of experimental medicine to discover the methods chosen by nature and to duplicate the physiologic reactions in experimental animals, where they can be more thoroughly investigated.

With such thoughts in mind, I propose to analyze a few common signs and symptoms of cardiovascular disease in the light of experimental studies, with a view of giving them a clearer meaning or an added significance.

TACHYCARDIA

An excessively rapid heart rate is a presenting symptom in such diversified conditions that it is important to determine at once whether a simple sinus tachycardia in which the origin and spread of impulses are normal is being dealt with or a form in which abnormal circuits or focal rhythmic impulses, as in auricular and ventricular paroxysmal tachycardias and in auricular flutter. Interesting differences occur also in the cardiodynamic mechanism, for while circulatory embarrassment rarely supervenes at heart rates of 250 per minute or over in sinus tachycardias, circulatory deficiency easily occurs at heart rates of 180 per minute or less in ventricular types of tachycardia.

Dynamic studies have shown that the faster the heart beats the more the period of diastolic filling is cut short and the more the systolic discharge is decreased. However, calculations show that this decrease is more than compensated by the cardiac rate up to 200 per minute,

so that the minute output becomes steadily greater. Only beyond this critical rate is the minute output reduced. The reason that the ventricles can fill at all at heart rates above 200 is that the heart muscle makes a remarkable adjustment. Calculations show that at a heart rate of 200 per minute the cycle length is only 0.3 second, or slightly more than the period of ejection at normal rates. Were it not for the fact that systole shortens progressively with increased rates, no interval for diastolic ventricular filling could exist.

Ventricular rates of 200 or less cannot maintain even a normal minute volume and result in circulatory embarrassment when an idioventricular rhythm is responsible for the tachycardia because of two factors. First, but less important, is the fact that ventricular filling is not aided by preceding synergic auricular contractions. Second, the abnormal spread of impulses over the ventricles produces a less efficient summation of fractionate contractions and consequently each systole develops less expulsive force.

Two dynamically different types of sinus tachycardia exist: (1) a form due to primary inhibition of the vagus or to stimulation of the accelerator nervous mechanism, e.g., that due to fear, to unstable conditions of the nervous system, to disorders of glands of internal secretion, to accelerated metabolism, to fever or to drugs; and (2) a compensatory form following a primary drop in blood pressure due to vasodilatation or reduced cardiac output. A clinical differentiation between these two physiologic types must be made by consideration of the entire clinical picture; it cannot be made from the degree of acceleration or from measurements of blood pressure alone.

Elementary dynamic considerations suggest that any increase in heart rate should theoretically produce an elevation of pressure. A significant rise of pressure is rarely found in human subjects, however; on the contrary, the blood pressure in the second type is often somewhat decreased.

This is due to the fact that the heart and peripheral vessels are reciprocally adapted to prevent more than moderate deviations from normal blood pressure levels. Whenever the heart rate increases and the blood pressure tends to rise reflexes are promptly set up from the larger arteries which invoke a vasodilatation. Conversely, when arterial pressures fall, due to primary vasodilatation or to diminished cardiac output, the heart accelerates and strives to restore arterial pressures to normal. Marek, who first noted this inverse relationship between heart rate and blood pressure, believed that it was due to a direct effect of the altered blood flow through the medulla. More recent work, however, has shown that nervous reflexes from the large vessels are chiefly concerned in producing such moderating effects on blood pressure. Two definite pathways are recognized, one over those afferent branches of the vagus which are distributed to the root of the aorta, the other over the so-called sinus nerve, a branch of the glossopharyngeal which is distributed solely to the enlargement of the common carotid artery as it divides into internal and external carotid branches. The second or compensatory type of cardiac acceleration is produced through these reflex mechanisms not only when peripheral vasodilatation exists but also when the systolic discharge of the heart is reduced. Shock and hemorrhage are two clinical conditions in which such a reduced output and compensatory acceleration obtain. But it is not so generally appreciated that the same reflex mechanisms operate when ventricular discharge

is reduced as a result of myocardial failure and that the tachycardia which is so characteristically present is nature's only method of maintaining an effective circulation. Aortic insufficiency presents another condition in which this compensatory type of acceleration obtains. Studies in my laboratory have shown that in this lesion it is doubly favorable, it not only augments the minute volume as in normal hearts but, by reducing the interval of diastole, decreases the reflux of blood into the ventricle.

A full appreciation of the physiologic significance of these forms of tachycardia is of the greatest importance. Without it, the physician is inclined to regard such a form of tachycardia as an unfavorable sign and is impelled to take steps to induce a slowing. It is obvious that this compensatory acceleration must not be disturbed. To do so would cause a drop in blood pressure sufficient, perhaps, to endanger life itself. Fortunately there is no medicinal agent by which a compensatory sinus tachycardia can easily be abolished, otherwise many a patient with serious heart disease would have been helped prematurely to his grave through kindly intentioned but misguided treatment.

PALPITATION

The normally contracting heart is a vigorously beating organ, as any one who has watched exposed hearts in animals will recall. With each contraction it not only develops sufficient tension to expel a considerable volume of blood, but it rotates and twists about in the chest and gives a sufficiently sharp thrust against the chest wall to permit its registration by graphic apparatus. But one normally remains quite oblivious of this rather vigorous impact, in fact, it is recognized only with difficulty when attention is specifically focused on the precordium. This is explained by the statement that one becomes accustomed to the impact, much as one becomes unaware of the tick of a clock. Expressed in physiologic terms, a partial fatigue of the receptive mechanism obtains, so that stimuli which originally excite become subminimal or below the threshold value.

In order to be recognized as palpitation, the accelerated heart action must therefore be accompanied by a more forceful thrust. This often—though not necessarily—implies a more vigorous beat of the ventricles. As a result of changes in rate, particularly when pronounced, the heart becomes smaller and shifts its position slightly, and in this wise the apex thrust can be delivered to better advantage. Or a similar phenomenon may result when the total force of contraction is actually reduced but the order of excitation is changed. Any abnormal distribution of impulses over the ventricles materially affects the motions of the heart as a whole and thereby the intensity of the apex thrust. I have often been impressed by the much more vigorous motions of the exposed ventricles of dogs when a ventricular tachycardia is induced experimentally. I believe I am correct in the statement that patients also complain far more frequently of palpitation when tachycardia is of ventricular origin. But dynamic studies show that the ventricular force is actually reduced, not increased.

VERTIGO, SYNCOPÉ, CONVULSIONS AND RELATED SYMPTOMS

Aside from primary disorders of the nervous system or chemical alterations of the blood, cardiovascular disorders are chiefly responsible for the symptoms of dizziness, unconsciousness or convulsions. Anoxemia of the cerebral centers resulting from a pronounced

fall of systemic blood pressures is the underlying cause. The cells of the cerebral cortex are extremely sensitive to a rather temporary but marked diminution of its supply of oxygenated blood and react promptly by manifestations of vertigo and unconsciousness. Experiments on dogs indicate that complete cessation of cerebral blood supply lasting more than eight minutes is only exceptionally followed by recovery. This is the reason that death follows so rapidly after ventricular fibrillation and that the revival of patients or animals after accidental electrocution presents such great difficulties.

Since the arterial blood supply is so intimately dependent on systemic pressures, any of the factors known to reduce arterial pressure, e.g., reduced systolic discharge, lowered peripheral resistance and decreased heart rate, can diminish cerebral blood flow beyond the critical level necessary to maintain cerebral functions. The syncope and convulsions that develop after severe hemorrhage and the fainting that occurs when a patient rises suddenly after convalescence are both due to a reduced venous return and a consequent reduction in systolic discharge. Extensive vasodilatation produced through nervous reflexes, as in fright or from administration of amyl nitrite, may lower systemic pressure sufficiently to produce tremors, convulsions or fainting. But sudden slowing or stoppage of the heart through psychic or reflex stimulation of the cardioinhibitory mechanism or through the development of complete auriculoventricular heart block are the most common causes of cerebral anoxemia. As a rule, unconsciousness and fainting are preceded by a period of dizziness and by ocular and auditory disturbances, the duration of which is inversely related to the degree of hypotension and to the rapidity of its development. During complete stoppage of the ventricles, the systemic pressure drops to zero within a few seconds and unconsciousness follows immediately. If the complete cerebral anoxemia is maintained beyond from fifteen to thirty seconds, recovery is always complicated by convulsions or epileptiform seizures. In short, the syndrome described by Stokes and Adams independently and often regarded as pathognomonic for heart block develops whenever the ventricles beat extremely slowly or stop entirely, regardless of the cause.

A physiologic analysis thus brings one to the realization that the symptoms of giddiness, syncope and convulsions are nature's method of announcing any considerable fall of arterial pressure, indeed, the reliability with which dangerous hypotension is thus registered cannot be equaled by the most careful application of blood pressure apparatus.

The unconsciousness and fainting that follow a lowering of systemic pressure are not only a warning signal they also set in operation an automatic mechanism for relief. Since unconsciousness goes hand in hand with a loss of voluntary muscular control, the patient in falling tends to assume a more horizontal position. The retarding effect of gravity on the return of blood being removed, the systolic discharge increases and, if the heart is beating at all usually elevates the arterial pressure above the critical level, thus consciousness is regained.

While symptoms of dizziness and fainting are commonly associated with disorders of the circulation that abruptly and rapidly diminish the cerebral blood flow they are rarely associated with the most serious valvular and myocardial conditions found in chronic heart dis-

case. The impairment of the cerebral blood flow and attendant anoxemia that ultimately develops lead to psychic phenomena of a different sort. A sense of mental haziness, impaired memory, stupor, drowsiness and hallucinations of sight, hearing and smell are among the more common symptoms noted. These forms of cerebral dysfunction are undoubtedly attributable to effects of moderate degrees of anoxemia. But that they are not newly developed manifestations is clearly demonstrated by the fact that all are acutely duplicated when normal individuals are submitted to the influence of high altitudes or low barometric pressures or are allowed to breathe low oxygen mixtures.

It has generally been supposed that nervous tissue has but a low metabolic role, that the brain consequently needs only little oxygen but needs that little badly. More recent experiments indicate, however, that the metabolism of the brain does not differ greatly from that of other tissue. The rate of lactic acid formation in brain tissue appears to be higher than that of the body as a whole, and the normal blood flow per gram of brain substance is larger than that of skeletal muscle, heart, spleen or liver, being exceeded only by that of the kidney, the suprarenal and the thyroid.

It is not surprising, therefore, that cerebral activity should be seriously affected in advanced stages of decompensation, it is rather surprising that cerebral manifestations are no more severe and that they do not precede decompensation. The absence of manifestations on the part of the most sensitive indicator of circulatory insufficiency—the cerebral cortex—is the best evidence a physiologist could cite in support of the conclusion that the circulation is physiologically at par until decompensation sets in.

FATIGUE

Fatigue after slight or moderate exertion or even at rest is a constant accompaniment of many forms of advanced heart disease. Its significance can be properly understood only through an analysis of a similar phenomenon occurring in health after strenuous exercise. The two are caused by the same underlying phenomenon, the only difference between the fatigue in health and that noted in patients with cardiac disease being the degree of exercise necessary to bring it on.

Although best usage restricts the term fatigue to a depression of physiologic function following activity, it is often loosely applied to general sensations that arise without relation to previous effort. The sensations of fatigue are known to every one, but it is not universally realized that they are but signs and symptoms of chemical changes that affect every tissue of the body. The glands, the sense organs and the central nervous system are just as susceptible to fatigue as the muscles. However, since the symptoms and disturbances of function are predominantly referred to the muscles, it is best to use the progressive decrease in the ability of muscles to contract as the criterion of what is going on in other cells of the body.

It has been demonstrated by different methods that the anaerobic production of lactic acid and its accumulation in muscular tissue is the ultimate cause of the progressive decrease in the strength of contraction. In intact animals, such an accumulation begins as soon as the demands of tissues for oxygen exceeds the ability of the circulatory and respiratory apparatus to deliver it. In the resting state of normal individuals the supply of oxygen always exceeds the demand and even

a considerable amount of muscular exertion may be undertaken before oxygen utilization equals the supply furnished through increased respiration and augmented circulation. When this occurs, a "steady state" is said to exist. In extreme exertion, on the other hand, the supply no longer meets the demand and an "oxygen debt" is incurred. Under such conditions, lactic acid accumulates chiefly in the muscles, but to a certain extent also in the blood. It is then that the signs and symptoms of fatigue develop. In short, decreased muscular efficiency and the sensations of fatigue are direct criteria of the existence of an oxygen debt and of the accumulation of lactic acid.

The more rapid development of fatigue in the presence of heart disease merely signifies a deficiency on the part of the cardiorespiratory system to meet the increased demands of the muscles during exercise. But since the respiratory apparatus functions in normal fashion except when secondary respiratory complications supervene, it is obvious that the heart and circulation are chiefly at fault. This circulatory deficiency does not, however, consist in an inability of the diseased heart to compensate, it is rather due to the fact that the heart's ability to augment minute output through acceleration or increased systolic discharge has already been called into action for the purpose of maintaining a normal circulation at rest. Hence, the physiologic ability to respond to exercise without the development of fatigue becomes a direct measure of the compensatory mechanism held in reserve by the heart, i. e., of its reserve power.

In a patient able to perform a moderate amount of work without fatigue the reserve power is good, a subject capable of only slight exertion has no great margin to call on, while the existence of continued fatigue even at rest denotes that all the compensatory mechanisms of the heart are unable to maintain an oxygen balance. The latter is the physiologic picture of cardiac decompensation. Clinical studies have shown that whenever this occurs the lactic acid content of the blood is increased even at rest, thus accounting for the perpetual existence of fatigue. Furthermore, it must be clear that the development of fixed acidosis in the bedridden patient is intimately linked with the phenomenon responsible for decompensation, as well as those that underlie muscular prostration.

DYSPNEA

Dyspnea is probably the symptom of greatest diagnostic and prognostic importance in heart disease. But it is also a phenomenon that occurs in normal individuals after strenuous exertion. The only distinguishing feature between the dyspnea of health and that associated with cardiac disease is the degree of exertion required to bring it on, indeed, in the most advanced cases of heart disease it is constantly present even during rest.

Consequently, one must return to the information gained by a study of dyspnea produced in normal animals or man in order to understand that which nature produces in disease. The rate and depth of the respiratory movements are adapted to the needs of the body through a center in the medulla. Normally, periodic volleys of impulses are sent down the cord and thence over the cervical and brachial nerves to muscles concerned with thoracic enlargement. But the intensity of the stimulation is not great enough to induce a maximum contraction in such inspiratory muscles as the external intercostals, the scaleni and the diaphragm.

Not is then strength sufficient to penetrate the more resistant pathways connecting with expiratory muscles. Hence expiration is a passive act. Now the normal intensity, sequence and duration of successive volleys of stimuli emitted by the respiratory center appears to be controlled by the intracellular C_{H^+} of this center. When the intracellular acidity increases for any reason the normal inspiratory muscles not only contract more frequently, more vigorously and for a longer time, but new groups of inspiratory muscles are likewise thrown into action. This gives rise to hyperpnea, i.e., an accentuated breathing in which the depth of inspiration is increased and the rate becomes more frequent. Finally, as the intracellular acidity of the respiratory nerve cells rises to still higher levels, the intensity of the stimuli sent forth arguments to such an extent that the pathways to expiratory muscles are also penetrated, and expiration becomes forced. I suspect that the unpleasant character of this type of breathing is partly associated with stimulation of unaccustomed proprioceptive endings as expiratory muscles are involved. I therefore prefer to limit the term dyspnea to that stage of deep breathing in which forced expiration supervenes. These considerations enable us to lay down a first postulate, viz., that dyspnea, whether recognized as a disagreeable symptom by a patient with heart disease or as a sign by the physician, presents physiologic evidence that the intracellular acidity of the respiratory center has increased considerably. Further, the corollary that the degree of dyspnea is roughly proportional to the increase in intracellular C_{H^+} .

The more difficult questions now arise as to how and why the intracellular acidity of the respiratory center is increased in cardiovascular disease. Experimental evidence indicates that this is determined (1) by the rate of acid formation, (2) by the rate of acid removal either through local oxidation or by mechanical export, (3) by the interchange of hydrogen ions between the blood and the respiratory cells and (4) by the buffering capacity of the cytoplasm comprising the respiratory center.

The first factor is probably concerned to the extent that the increased activity of the respiratory center results in an increased intracellular acidity and so assists in continuing dyspnea once it is inaugurated. But this can obviously not be at once a primary cause and in effect. Some other factor must be initially responsible.

The second factor must be carefully evaluated in the light of all clinical knowledge. Two mechanisms are conceivable: (1) owing to a sluggish circulation an inadequate supply of oxygen may reach the center and hence the acid formed within the center may fail to be properly oxidized; (2) owing to a diminished arterial pressure and an increased venous stasis, lactic acid may not be washed away easily.

The first process is a remote possibility and can be concerned only in advanced decompensation, for as already pointed out the oxygen supply appears to be adequate to support normal cerebral processes and ipso facto is likely to be sufficient for the respiratory center. The latter may be concerned somewhat earlier and may possibly be responsible for orthopnea as will presently be explained. But at the best such moduli operandi are difficult to picture except during comparatively advanced stages of circulatory failure. The advent of dyspnea particularly after light exertion occurs before any evidence of circulatory embarrassment can be

detected. It is present when arterial pressures, minute volume, blood flow and circulation time measurements are practically normal, and before venous pressures are elevated or stasis is evident. Indeed, diminished ability to partake of moderate exercise without the occurrence of marked dyspnea is a symptom in many forms of incipient heart disease.

A consideration of the third factor, the possibility that the acidity of the respiratory center may be altered by changes in the chemical composition of the blood, recalls the usual current conceptions, viz., that an excess of fixed acids or an increase of carbon dioxide are chiefly responsible for the phenomenon of cardiac dyspnea. But as to the relative importance of the two, the best clinical opinions appear to differ. And well they may in view of the fact that some cardiac patients show a diminished carbon dioxide content of the arterial blood while other equally dyspneic patients present no evidence of fixed acidosis.

But at this juncture distinctions must be made clear. There is no doubt that dyspnea easily induced by exercise is always associated with hypercapnia. The quandary arises chiefly in explaining the persistent dyspnea of resting cardiac patients who present distinct evidence of lactic acid accumulation but show only a normal or diminished carbon dioxide content of their arterial blood.

It is obvious that the interchange of hydrogen ions between the blood and the respiratory center involves both the p_{H^+} of the blood and the relative rates with which ions diffuse from the circulating blood into the respiratory cells. For a long time the view held sway that the acidity of the respiratory center is regulated solely by the hydrogen ion content of the blood and that somewhat similar effects might be expected from a definite change in blood C_{H^+} , whether due to an increase of fixed acids or carbon dioxide or to a decrease in bicarbonate. Such a parallelism between changes in blood C_{H^+} and respiratory activity could be expected, however, only if the metabolism of the center were low and all ions diffused with equal facility. The bulk of experimental work indicates that this conception is untenable and that there is no conspicuous relation between C_{H^+} changes of the blood and activity of the respiratory center; indeed, injections of sodium bicarbonate which decrease C_{H^+} of the blood may, under certain conditions (e.g., hemorrhage), act as a respiratory stimulant. On the other hand, elaborate experimental work has never succeeded in controverting the idea that the respiratory center responds promptly to small changes in the carbon dioxide content of arterial blood. This is undoubtedly due to the greater ease with which carbon dioxide or the bicarbonate ion diffuse into cells.

In view of these considerations it is highly improbable that the degree of fixed acid acidosis encountered even in uncompensated cardiac crises is capable of producing alterations in the C_{H^+} of the respiratory center sufficient to account for the dyspnea. In the first place the degree of acidosis is never equal to that encountered in diabetes and yet dyspnea is not a conspicuous feature in the latter disease. Furthermore, slow intravenous injections of lactic acid into experimental animals to a point just compatible with life never produce dyspnea provided a natural compensatory blowing off of carbon dioxide is allowed to take place. On the other hand, if the free discharge of carbon dioxide is interfered with, or if the rate of carbon dioxide production is

stimulated, violent dyspneic symptoms at once occur. Under such conditions even a normal carbon dioxide content of the blood is accompanied by pronounced dyspnea. This perhaps supplies a key to the interpretation of dyspnea in resting clinical patients. Neither an excess of carbon dioxide, as in exercise, nor the existence of a fixed acidosis is separately responsible for the dyspnea. But a moderate grade of fixed acidosis combined with pulmonary congestion which prevents the compensatory elimination of carbon dioxide might easily produce augmented breathing in heart disease. Such a conception makes it possible to link up the coexistence of pulmonary congestion, encroachment on alveolar air spaces, and a reduced vital capacity. It also explains why improvement of the circulation, greater ease in respiration and an increase in vital capacity go hand in hand.

In the light of this conception also it appears to be a basic fact that impairment of the pulmonary circulation is the ultimate cause that prevents the free compensatory elimination of carbon dioxide. Were it possible to analyze the detailed dynamic changes that occur as decompensation progresses, it would probably also be found that the grade of dyspnea is roughly related to the decreasing efficiency of the heart. Thus, through physiologic analysis the conclusion is reached that the degree of dyspnea experienced by a cardiac patient at rest offers the simplest and most accurate method of measuring the performance of the heart pump.

ORTHOPNEA

The fact that the dyspnea of advanced heart disease is materially aggravated in the recumbent position must have attracted the attention of ancient observers. Nevertheless, knowledge as to the physiologic causes of this curious phenomenon is still meager. It furnishes a glowing example of the retardation of medical progress when clinical conditions do not lend themselves readily to experimental study on animals. As is usual, numerous theories as to its etiology are not lacking and one can do no better at present than to consider how well each fits into the clinical picture and is consonant with physiologic facts.

One conception holds that the sitting posture acts mechanically to increase the reserve air in the lungs, i. e., the volume content with the chest wall in the normal expiratory position. By increasing the mean volume of gases in contact with lung capillaries this should favor a better interchange of oxygen and carbon dioxide. Such an increased pulmonary capacity is attributed chiefly to the lower position of the diaphragm. This theory is supported by the observation that negative intrathoracic pressures are less, and in a measure by the finding that the vital capacity is somewhat increased on assumption of a sitting position.

According to a second conception, which is really an extension of the former, the increased elastic stretch of the lung by descent of the diaphragm, combined with the mechanical advantage gained for the shoulder and abdominal muscles, facilitates the act of forced expiration. This view is supported by the belief that the difficulty in orthopnea affects the act of expiration rather than the act of inspiration.

A third theory stresses the fact that a more perfect unfolding of the lungs occurs in the upright position. Attention is directed to the fact that imperfect alveolar ventilation tends to occur even in normal individuals in a recumbent position and that a tendency to slight

anoxemia is rectified only by periodic deeper inspirations. To account for orthopnea on this hypothesis, however, it is necessary to assume that the inspiratory compensation is abrogated, an assumption for which there is no sound physiologic basis.

In contrast to those theories which attribute orthopnea to benefits from the mechanical mechanisms involved in the interchange of air, a fourth conception holds that improvement is due to a better minute flow of blood. This is supposedly accomplished by an enlargement of the aperture of the vena cava as the diaphragm assumes a lower position. Experimental work makes it exceedingly doubtful, however, that the latter mechanism materially improves the venous return. But this would appear to be immaterial in decompensation because the amount of blood available for filling is already in excess, owing to venous engorgement. Deficiency in venous return is not the cause of diminished ventricular discharge in cardiac failure, and it is quite incomprehensible how it could enhance the minute volume. This hypothesis may therefore be disregarded.

Finally, the view has recently been advanced that the sitting position benefits respiration because gravity favors a drawing of blood from the head and in so doing relieves venous congestion and improves the flow through the respiratory center. In this way, acid metabolites found within the respiratory center would more easily be washed away and the C_{H_2} of the respiratory center would decrease. Ernstene and Blumgart may be congratulated in offering an explanation of orthopnea which accords so well with recent physiologic evidence that the control of the respiratory mechanism is effected through changes in intracellular C_{H_2} . It is to be hoped that they may have added opportunities for adducing still more valid evidence in its support.

An understanding of the cause of orthopnea is more than an academic accomplishment, it involves more than the mental gratification which always follows a solution of nature's mysteries. The ultimate physiologic meaning of the phenomenon for the body as a whole is concerned in the solution of the riddle. If the sitting posture relieves dyspneic breathing through mechanical respiratory mechanisms, then the asphyxial distress in the recumbent position is necessarily associated with asphyxial changes in all tissues of the body. But if it is due to medullary stasis, it does not necessarily predicate a condition of generalized asphyxia. In other words, is the asphyxial distress experienced by orthopneic patients to be interpreted as evidence that a condition of general tissue asphyxia is already in progress or is it an advance warning of such an impending misfortune? Does a patient by assuming a sitting posture alleviate an existing asphyxial condition or does he thereby prevent its occurrence? These and similar far reaching questions are involved in a clearer physiologic understanding of orthopnea.

CYANOSIS

Cyanosis is one of the conspicuous clinical signs in a variety of cardiac disorders but is present in most pronounced form in mitral disease and in congenital defects of the heart. Its diagnostic significance is intimately bound up with the fact that the mucous membrane and skin over favorable parts of the body form a natural colorimeter by which the degree of oxygen saturation or unsaturation of capillary blood can be easily and directly evaluated.

The color of the skin is not a perfect colorimeter, however, since it is determined not only by the quantity

of reduced hemoglobin in the capillaries but is modified also (1) by the thickness and pigmentation of the layers overlying the smaller vessels and (2) by the number, diameter and length of the capillaries themselves. The effective blood pigment which transmits the bluish or purplish tinge to the surface of the skin is reduced hemoglobin. Lundsgaard has shown that when the hemoglobin content falls below 30 per cent cyanosis cannot develop, which explains its absence in valvular disease complicated by anemia. These factors must be carefully evaluated in employing the color of the skin as a criterion of oxygen unsaturation of capillary blood.

If we leave out of consideration changes in the character and total amount of hemoglobin—which is permissible for our purposes—an abnormal amount of reduced hemoglobin in the capillaries is due either to an abnormal oxygen unsaturation of the arterial blood or to an increased rate of oxygen abstraction by the tissues. There is no doubt that deficient saturation of arterial blood or a state of anoxic anoxemia is chiefly responsible for the cyanosis found in congenital cardiac defects and in advanced forms of myocardial and mitral disease. In these instances, nature but duplicates the reactions that normal individuals show when submitted to low oxygen tension. Many clinicians and experimenters whose opinions carry great weight believe that this is also the cause of cyanosis in earlier stages of compensated mitral disease. The conception is generally held that pulmonary congestion which begins with the very onset of mitral stenosis diminishes the interchange of oxygen to such a degree that arterial blood is not fully saturated. Careful analysis of blood drawn from the radial arteries of such patients indicates, however, that complete saturation obtains unless decompensation supervenes or pulmonary emphysema complicates the picture. It is therefore impossible to attribute the early cyanosis of mitral disease to anoxic anoxemia. In short, it should be constantly kept in mind that, while cyanosis gives unfailing evidence of unsaturated capillary blood and probably of anoxemia of the tissues, it does not necessarily indicate that arterial blood is unsaturated. Such knowledge is of practical importance, for the presence of cyanosis in compensated mitral disease does not imply that an existing pulmonary congestion has progressed to the extent that a satisfactory interchange of oxygen is interfered with.

Since the cyanosis in compensated mitral disease cannot be referred to anoxic anoxemia, other causes must be sought. It has been suggested that the decreased output of the heart leads to diminished flow through the tissues and that this may be a cause. There are two valid objections to such a conception. In the first place, reduced minute discharge of the heart in normal subjects, whether due to slowing or to reduced stroke volume, is marked by pallor, not by cyanosis. In the second place, gasometric determinations of minute volume and measurements of blood flow in the extremities fail to demonstrate any diminution. Until clearer evidence is submitted in its support the hypothesis that diminished cardiac output is responsible for cyanosis cannot be accepted.

Cyanosis may be produced in normal subjects by inducing a more rapid utilization of oxygen. Since the metabolic rate of the entire body is often increased in patients with cardiovascular disease the possibility must be considered that the greater demand of oxygen by tissues of the skin may cause greater oxygen depletion of capillary blood. But it is difficult to understand how cardiac involvement alone can produce alterations

in the metabolism of tissues in general, it is far more probable that the observed increase in basal metabolism is due entirely to increased muscular action associated with dyspnea.

Venous congestion when present is one of the important factors in intensifying the cyanosis of mitral disease. By retarding the capillary flow, blood remains longer in contact with the tissues and hence is more completely robbed of its oxygen. But this does not fully explain the earliest evidence of cyanosis recognizable long before venous pressures have risen or clinical evidence of venous congestion exists. Partly by a process of exclusion and partly because cyanosis develops primarily over commonly exposed portions of the body, it must be inferred that some peripheral vascular factor capable of slowing the capillary blood stream must be concerned. Neither the causes nor the physiologic mechanisms are understood, however.

It should be kept in mind that the state of tissue anoxemia, mirrored in the intense cyanotic color of the skin during cardiac decompensation, exists also in internal organs and eventually disturbs their functions to such a degree that so-called secondary symptoms are produced. Among these are anorexia, flatulence, nausea and vomiting, and jaundice. But among all the secondary phenomena for which decompensation is noted oliguria and edema stand out predominantly.

OLIGURIA AND EDEMA

An adequate discussion of these early and constant manifestations of cardiac failure cannot readily be compressed into a short space. Nevertheless an analysis of the physiologic manifestations of heart disease would be incomplete without such an attempt. As is well known, the urinary secretion in advanced stages of heart disease becomes greatly reduced in amount, is highly concentrated and dark, and frequently contains albumin. Functional kidney tests show decreased function of the kidneys, especially as regards their ability to excrete water and salts.

In order to understand the physiologic reasons for this it is necessary to recall that, according to modern theories of urinary secretion, the glomeruli filter out a dilute urine containing all the constituents of the blood plasma with the exception of the colloids. In passing through the tubules, water and certain useful substances are reabsorbed, while others no longer of value in the physiologic economy of the body are passed on and excreted. The rate of glomerular filtration is governed by (a) the effective glomerular pressure, i.e. the hydrostatic capillary pressure minus the osmotic pressure exerted by the blood colloids, (b) the number of glomeruli in operation and (c) the physical characteristics of the capsular membrane.

The first two factors are probably not concerned greatly in producing the oliguria of chronic heart disease. But since the kidney glomeruli are extremely sensitive to lack of oxygen their permeability is altered by an impaired renal circulation. The appearance of albumin in the urine is one of the first evidences of such a change. But this does not necessarily imply an increased permeability to crystalloids and water, on the contrary their excretion tends to be decreased. Such a condition is especially unfortunate as it leads to the retention of water, salts, acid radicals and nitrogenous waste products which favor the development of acidosis, uremia and edema.

With failure of the kidneys to eliminate water and salts in adequate amounts, it is but a step to assume that

this accounts for the edema, in other words, that it is essentially of renal origin. However, the cardiovascular edema does not admit of so simple an interpretation, the deficient urinary excretion is at most a secondary factor. The primary cause is associated with inadequate return of blood to the heart. But the exact mechanism through which stasis causes edema is still under discussion. Following the lead of Ludwig and later of Starling, physiologists quite generally believed that edema due to stasis is explainable by the physical processes of filtration and osmosis. While these physical processes undoubtedly contribute, the trend of recent investigations strongly suggests that Cohnheim was probably right when he suggested that altered permeability of capillaries due to anoxemia or malnutrition must occur. Briefly, the essential facts may be stated thus: As a first step, dilatation of peripheral capillaries occurs, this is followed by changes in permeability of such a nature that the passage of water and salts from the blood stream is facilitated but then reabsorption is impaired, in short, edema is a definite physiologic sign that circulatory failure has progressed to such a stage that the life processes of many body cells are beginning to suffer.

CARDIAC PAIN

An intelligent discussion of cardiac pain is not at present possible, for ideas as to the ultimate mechanisms producing pain remain wholly speculative, the anatomic pathways for pain impulses are not known with certainty, and physiologic facts with regard to the nervous mechanisms are extremely meager. Nevertheless, patient clinical observations and experiences derived from attempts at surgical relief, combined with more limited experimental data on animals, have furnished a working hypothesis in regard to the mechanisms of cardiac pain. The viscera are apparently not supplied with afferent fibers that ordinarily relay pain sensations directly to the cortex. Under certain conditions—not at all clearly understood—afferent impulses from the viscera may, however, form synaptic connections with the posterior root ganglion cells. In so doing they give rise to pain sensations that are not referred to the organs from which they arise but to somatic areas innervated by sensory fibers of the posterior root ganglion cells with which contacts are made. In addition, the constant bombardment of posterior root cells produces in them a state of hyperexcitability with the result that hypersensitivity and often reflex muscular rigidity develop in the somatic regions supplied by the spinal cord segments involved. If the stimulation of viscerosensory terminals becomes very severe, cells in contiguous spinal segments may be affected in which case the referred pain and hyperesthesia involve larger skin areas.

In this way it is possible to explain why referred pains resulting from stimulation of afferent cardiac nerves are sometimes distinctly limited to circumscribed regions below the sternum and over the pericardium and at other times spread over the whole left side of the chest, or even radiate down the left arm and up the neck as far as the mastoid region.

A careful study of the distribution of such pains and of the hypersensitive areas indicates that as a rule, spinal segments between the eighth cervical and the fifth dorsal are involved. Occasionally, however, involvement may extend upward as far as the second cervical and downward as far as the seventh dorsal segments. Since the inferior and middle sympathetic nerves to the

heart also reach the spinal cord between the eighth cervical and seventh dorsal regions, it was logical to assume that pain impressions from the heart travel over these roots rather than over the vagus and depressor nerves.

While this interpretation has received a measure of support from neurologic, physiologic and clinical studies, many facts seem to indicate that other pathways also may be concerned. Were this the only route, more consistently good results might be expected from surgical sympathectomy and enucleation of sympathetic ganglions. Cutler, reviewing the subject from a surgical as well as a physiologic standpoint, aptly remarks: "The failure of any procedure to alleviate pain in all cases leaves us with the definite impression that much more is to be learned."

But aside from this uncertainty there is also lack of information as to the distribution of sensory branches. Histologists have so far discovered no nerve terminals in the ventricular myocardium or its blood vessels that can safely be inferred to carry afferent impulse. Chiefly for this reason, Sir Clifford Allbutt maintained to the end of his life that cardiac angina could arise only from stimulation of the nerve fibers terminating in the outer coats of the aorta. But a great deal of clinical and even a little experimental evidence exists that anoxemia of the heart muscle—regardless of whether it is produced by coronary embolism, thrombosis or sclerosis or whether it is due to cardiac failure, overexertion and tachycardia—is capable of inaugurating serious attacks of cardiac pain.

Should it be assumed that as yet unrecognized sensory fibers are distributed with motor and vasomotor fibers along the course of blood vessels? Or is it necessary to revise the physiologic conceptions that supposedly efferent sympathetic fibers terminating in muscle cells or blood vessels may carry afferent impressions? Finally arises the question as to how anoxemia can produce stimulation. If through a rapid formation of lactic acid which is known to enhance irritability only temporarily and then to depress it, why does the pain persist, and why is it periodic rather than constant? Clearly, factors quite unknown appear to act as the physiologic irritants of intracardiac terminals, wherever situated.

Fundamental questions such as these must be solved hand in hand with clinical questions of a seemingly more practical nature before the meaning of cardiac pain can be elucidated. But the importance of a scientific method of approach should not be forgotten. New facts must be established for their intrinsic worth rather than with a view of supporting a favored theory.

Beaumont, whose patience and perseverance for the sake of science and humanity is being honored today, expressed this well in the preface to his book when he said: "They [i.e., my researches] are experiments made in the true spirit of inquiry, suggested by the very extraordinary case which gave me an opportunity of making them. I had no particular hypothesis to support, and I have therefore honestly recorded the result of each experiment exactly as it occurred. I submit a body of facts which cannot be invalidated. My opinions may be doubted, denied, or approved according as they conflict or agree with the opinions of each individual who may read them, but their worth will be best determined by the foundation on which they rest—the incontrovertible facts."

May we as seekers of scientific truths in medicine have the wisdom to reflect often upon these sentiments!

Clinical Notes, Suggestions and New Instruments

FATAL THYROID CRISIS FOLLOWING INJECTION OF A VARICOSE VEIN

EATLE I. CREENE, M.D. AND J. MAJOR GREENE, M.D.
CHICAGO

One of the most dreaded and serious complications of exophthalmic goiter or primary hyperthyroidism is the acute thyroid crisis. It is a well established fact that acute thyroidism usually occurs in patients in whom the disease has been present and may often be precipitated by apparently minor events. Acute thyroid crises have been known to follow fatigue, intercurrent infections and mental or physical stimulation and fatal crises have been known to occur following an automobile accident, an attack of influenza, an attack of tonsillitis, the opening of a peritonsillar abscess, or an operation for acute appendicitis.

Thyrotoxic patients are poor risks when any form of treatment not aimed at the elimination of the thyrotoxicosis is attempted. It is recognized that even the simplest procedures, unless absolutely necessary, should be postponed until the hyperthyroidism is controlled, for fear of precipitating an acute hyperthyroidism.

This is a report of a fatal case of thyroid crisis precipitated by the injection of a varicose vein. A review of the literature fails to reveal a similar case. Complications following the injection of varicose veins are so uncommon that the average practitioner is injecting various solutions with apparent impunity, not realizing that danger often lingers in the offing.

REPORT OF CASE

G. C., a man, aged 40, was referred to one of us with a diagnosis of hyperthyroidism. The history was that he had been well until eight months before he presented himself. He then became nervous, complained of tachycardia, loss of 20 pounds (9 kg.) exaggerated appetite, weakness, exophthalmos, increased sweating and tremor.

Examination showed the patient to be fairly well nourished. There was a moderate exophthalmos with positive von Graefe, Stellwag and Moebius signs. The lungs were normal. The heart was slightly enlarged to the left. There were no murmurs. The abdomen was normal. The pulse rate was 142. The blood pressure 160 systolic and 80 diastolic. There was a small ulcer in the region of the left ankle which had broken down two months before. A number of small veins were present, particularly at the upper margin of the ulcer. Urinalysis was negative. There were 4,800,000 red cells with 9,800 white cells. The differential count was normal. The Wassermann and Kahn tests were negative. The basal metabolism test was plus 66. He was advised to enter the hospital to be prepared for thyroidectomy.

Because of pain in the ulcer on the leg the patient asked to have the veins injected. He had previously had an ulcer which had been treated by injection and Unna's boot with complete relief. The ulcer had remained healed for approximately ten months only to break down again two months previously. We refused to inject his veins in the presence of a high grade thyrotoxicosis but advised him to enter the hospital. He was told that during his stay in the hospital (while being treated with compound solution of iodine) in Unna's boot would be applied. We felt confident that during this period in bed before and after his operation the ulcer would probably heal. It however there was failure to heal after this period we would then consider injecting the small vein in the region of the ulcer. The patient acquiesced and promised to enter the hospital the following day. Unfortunately this was not done.

Two days later one of us was called by the patient's wife who informed us that her husband was seriously ill. The patient was found desperately sick thrashing about in bed delirious vomiting almost constantly with diarrhea flushed hot skin and marked exophthalmos. The pulse was so rapid that it was difficult to count. The temperature was 104.2 F by axilla.

From his wife it was learned that on the evening after leaving our office he went to a neighboring physician and asked to have the veins injected. This was done. Within a few hours he complained of terrific pain at the site of injection. The physician was called and gave directions to apply hot wet dressings to the ankle. Several hours later the man became very restless, perspired profusely and began to vomit and to have a distressing diarrhea. Later the restlessness became extreme and was followed by delirium.

Examination of the site of injection revealed an inflamed reddened area at the upper border of the ulcer, undoubtedly an extravasation of the injected material.

As we were unable to give the patient iodine either by mouth or by rectum, a stomach tube was inserted and compound solution of iodine was given in this manner. Within ten hours, approximately 100 cc of the solution was given. Five hundred cubic centimeters of 1 per cent dextrose in physiologic solution of sodium chloride was given intravenously. Morphine in one-fourth grain (0.015 Gm.) doses was given to control the nervousness. The patient seemed to rally somewhat, but the following morning his condition was more critical. Sodium iodide was given intravenously (7½ grains or 0.5 Gm.), repeated twice. The patient was pricked in ice in an attempt to reduce the hyperpyrexia, which had now reached 105.4 F by axilla. In spite of all our measures the patient rapidly sank, going into a deep coma, and died.

SUMMARY

1. Thyroid crisis is one of the most serious complications of thyrotoxicosis.

2. All procedures unless absolutely necessary, should be avoided until the thyroidism is controlled.

3. A fatal case of crisis developed from an injection for varicose veins.

MERCURIC CHLORIDE POISONING WITH RECOVERY FOLLOWING THE USE OF SODIUM THIOSULPHATE

HOWARD E. MARCHBANKS, M.D. C. HERBERT SMITH, M.D. AND
HARRY L. CHURCH, M.D. PITTSBURGH, PA.

As one goes through the literature on mercuric chloride poisoning, one is struck with the comparatively few patients who have survived massive doses of the drug. For this reason we report this case because in some respects, which will be brought out, we believe it to be unique.

The literature is so vast that to attempt to review it would be beyond the scope of our intentions. However in preparing this report we have scanned the literature on the subject and find few, if any, cases reported in which the patient has taken as large an amount of the poison and retained it as long as our patient did and recovered.

Havman and Priestly¹ reported a case in which the blood urea nitrogen reached 247 mg. on the nineteenth day of treatment and on infusion of physiologic solution of sodium chloride the urea nitrogen was reduced to 83 mg. and eventually came to normal leaving no damage to the kidneys. Both kidneys had been decapsulated in this patient with apparently little result.

In 1920 Ravaut² described the influence of small injections of sodium thiosulphate on the course of a severe arsenical dermatitis. This report was followed in 1922 by that of McBride and Dennis³ in which a regular and sustained course of sodium thiosulphate was advocated for the emergency and follow up treatment of arsenical, mercurial and lead poisoning.

In 1928 Goldblatt⁴ reported the results of his experiments on the emesis interval in mercurial poisoning. He stated that in cases in which the patient had not vomited within thirteen minutes the prognosis was bad. In six fatal cases reported the shortest interval was 15 minutes and the longest was 120 minutes. None lived with an interval over 15 minutes.

² Ravaut, P. *Pres. med.* 25: 73 (Jan. 28) 1920.

³ McBride, W. L. and Dennis, C. C. *Treatment of Arsenical Dermatitis and Certain Metallic Poisoning*. *Arch. Derm.* 63: 163 (Jan.) 1923.

⁴ Goldblatt, S. *Clinical J. Med.* 17: 245 1928.

Hunter,⁵ in 1927, reported a fatal case of poisoning with mercuric chloride in which at autopsy on the fourteenth day, he found there was practically complete regeneration of the tubular epithelium.

However, Harmon,⁶ in 1928, describes the pathologic changes of the kidney in four fatal cases of mercuric chloride poisoning in which intravenous injection of dosage over 5 mg per kilogram of body weight had been given. He found degeneration and necrosis in the tubular epithelium of all four cases. The most severe lesions were seen in the proximal and distal convoluted tubules. The glomeruli apparently escaped.

Weiss,⁷ in 1924, reported a series of 135 consecutive patients poisoned by some form of mercury with only 8 deaths. These patients took from 1½ to 50 grams (from 0.1 to 31 Gm) of mercuric chloride. In only fifteen patients did a complete suppression develop. Of these, seven died. The patients who had the greatest difficulty were of the group that took more than 30 grams (2 Gm) and those in whom the institution of treatment was delayed. The treatment used by Weiss was the intravenous injection of large doses of Fischer's solution namely, crystallized sodium carbonate, 10 Gm sodium chloride, 15 Gm, distilled water, sufficient to make 1,000 cc, along with other alkali mixtures by mouth.

Rosenbloom,⁸ in 1919, described a method of treatment that depended chiefly on the use of alkalinization for its benefits. Great credit is due these early workers for the progress they made.

Kahn,⁹ in 1915, reported a case in which a Greel had committed suicide by taking from 25 to 50 Gm of mercuric chloride. An autopsy was done, the observations of which he reports. He likewise gives the amount of mercury that was recovered from the vomitus, the stool washings and the urine. He also gives the amount of mercury found in every organ of the body, including even the skin and the hair. He found that the liver contained the greatest amount, 303 mg of mercury, the intestines next, 81.48 mg and the brain third, with 59.9 mg. After these were the kidneys, lungs, spleen and pancreas. The other organs contained only small amounts.

This covers only a small amount of the literature on the subject but brings up a few of the more important things about poisoning with mercuric chloride.

REPORT OF CASE

An American housewife, aged 21 was brought into Mount Carmel Hospital at 3 30 p. m., Feb 4, 1930, suffering with a severe pain in the abdomen and vomiting. She had eaten a little lunch at 2 p. m. on the previous day and at 5 o'clock, three hours after the lunch, she took ten 7½ grain (0.5 Gm) tablets of mercuric chloride with suicidal intent. She first took five tablets and drank a little water. She then took five more and drank

TABLE 1—Urine Examinations

	Specific Gravity	Albumin	Red Blood Cells	Granular Casts	Renal Cells	Waxy Casts
2/ 4/30	1.016	3+	0	3+	4+	0
2/ 5/30		4+	0	4+	4+	0
2/ 6/30		2+	2+	2+	4+	0

2/21/30	1.010	0	0	+	2+	0
3/ 3/30	1.012	0	0	0	0	0

water again. She took about a glassful of water in all. About twenty minutes after she took the tablets she vomited. Ten minutes later she was in a physician's office, where she was given medicine to make her vomit. The physician also gave her milk. She then drank a lot of milk and coffee and ate one soft-boiled egg. Her bowels had moved once or twice before she came in. She did not notice that any blood was in the vomitus but she did notice blood in the stool.

Treatment was begun by one of us (C. H. S.) at once. She continued to vomit blood and mucus for several days. She was given sodium thiosulphate 10 cc intravenously every eight

hours until she had had five doses. She was given no other intravenous medication. Her diet was chiefly egg albumin in orange juice, milk and buttermilk. She vomited blood clots daily, and in fairly large amounts. She also passed from four to seven bloody or black stools daily. This continued until February 7, after which very little blood was seen in the stool and vomiting ceased. There was not at any time a complete suppression of urine although she passed only small amounts on the second and third hospital days.

TABLE 2—Results of Chemical Examinations of the Blood

	Nonprotein Nitrogen Mg	Creatinine Mg	Uric acid Mg
2/ 5/30	170	4.2	61
2/ 6/30	200	6.4	
2/ 10/30	270	7.8	80
2/12/30	300		
2/17/30	100		
2/18/30		1	97

On entrance the physical signs were not remarkable. The patient was fairly well frightened, but her temperature was 98 F, pulse 100, respiration 22. Her abdomen was not distended and except for the vomiting she seemed fairly well. Phenolsulphonphthalein 1-hourly 11 was 0 in two hours. The red blood cells became low as a result of the loss of blood.

The clinical course of the patient is better shown by the laboratory reports than in any other way. She seemed com-

TABLE 3—Red Cell Count

	Red Blood Cells	Hemoglobin
2/14/30	3,800,000	
2/18/30	3,140,000	40 per cent
2/21/30	1,800,000	20 per cent

fortable most of the time and took liquids freely most of the time including buttermilk, broth, egg albumin with orange juice, and pop.

On the fifth hospital day she complained of numbness, but by the next day she was feeling well again although her nonprotein nitrogen was 300 mg and her creatinine was 78 mg per hundred cubic centimeters of blood.

She constantly lost blood by the bowels. At no time was there a complete suppression of urine.

By the seventeenth hospital day, February 21, she had lost so much blood that a transfusion of 510 cc of blood was given by the direct method. A second transfusion of 525 cc was given March 1.

February 17 the nonprotein nitrogen had gone down to 50 mg and except for the constant bleeding she was in good condition. After the second transfusion the bleeding ceased. She left the hospital, March 3, in good condition.

She had made plans before leaving the hospital to visit in a distant city so that there would be no temptation for repeating her act.

July 28, she sent the following laboratory report, which we had suggested that she get. The urine was free from albumin, nonprotein nitrogen was 26 mg per hundred cubic centimeters of blood, creatinine, 18 mg per hundred cubic centimeters of blood, phenolsulphonphthalein, 50 per cent in one hour.

SUMMARY

1 A woman took 75 grains (5 Gm) of mercuric chloride.
2 She had retained the poison twenty minutes (not actual time, but by guess), before she vomited at all and thirty minutes before she had an emetic.

3 The nonprotein nitrogen reached 300 mg and the creatinine 78 mg on the seventh day after the poison was taken.

4 Fifty cubic centimeters of sodium thiosulphate in five doses seemed to have neutralized the mercury and saved the patient's life.

5 Six months after taking the poison the patient has normal kidney function and has no symptoms that are traceable to the mercury.

Council on Pharmacy and Chemistry

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

W. A. PUCKNER, Secretary

MARINE LIVER EXTRACT-WHITE — A liver extract representing the water soluble fraction obtained from the livers of fish of the *Gadus* family in a glycerol-water solution. 100 cc represents fresh liver, 3,027 Gm (1 fluidounce represents 2 pounds avoirdupois).

Actions and Uses — Controlled clinical observations show that in pernicious anemia rapid improvement may be expected following the administration of marine liver extract-White. The first change following administration is a rise in the reticulocyte curve beginning from four to seven days after commencement of treatment following this the erythrocyte and hemoglobin curves rise and gradually approach the normal. Marine liver extract-White is an effective substitute for the feeding of whole liver.

Dosage — The average daily therapeutic dose is 90 cc (3 fluidounces). After the reticulocyte peak is reached, the therapeutic dose is gradually diminished and the maintenance dose established by a careful observation of the red blood cell count. The preparation may be administered cooled with cracked ice or in chilled orange juice. Rectally 45 cc (1½ fluidounces) may be administered twice daily in 60 cc (2 fluidounces) of warm milk.

Manufactured by White Laboratories, Inc., Gloucester, Mass. (Health Products Corporation, Newark, N. J. distributor). No U. S. patent or trademark.

The residue remaining after extraction of the oil from livers of fish of the *Gadus* family is extracted with water. The aqueous extraction is adjusted to the isoelectric point (pH 5 to 6), heated to 80°C and filtered. The filtrate is reduced under diminished pressure to a small volume and sufficient 95 per cent alcohol added to produce an alcoholic concentration of 60 to 70 per cent. The precipitate is removed by filtration and discarded and the filtrate reduced under diminished pressure at a temperature below 60°C until the residue has a specific gravity of 1.22 at 43°C. The residue is dissolved in glycerin and water added so that 100 cc shall represent 3,027 Gm of the fresh liver and contain 40 per cent of glycerin by weight.

Marine liver extract-White is a dark amber liquid slightly viscous and having a characteristic odor of liver.

Each lot of marine liver extract-White is tested for potency by clinical trials and none is issued unless found of satisfactory potency when administered in the recommended dosage.

POLLEN EXTRACTS-ARLCO (See New and Nonofficial Remedies, 1930, p. 29)

The following products have been accepted:

Grass Mixture No. 1 Pollen Extract Arlco (Timothy, June Grass, Orchard Grass, Red Top, in equal parts) Grass Mixture No. 2 Pollen Extract Arlco (Timothy 40 per cent, Orchard Grass, Red Top, and Sweet Fernal Grass, each 15 per cent) Grass Mixture No. 3 Pollen Extract Arlco (Bernuda Grass and Johnson Grass in equal parts) Ragweed Dwarf and Giant Mixture Pollen Extract Arlco (equal parts of each) Ragweed Mixture Plus Burdock and Marsh Elder Pollen Extra Arlco. Spiny Inuaranth Pollen Extract Arlco. Western Water Hemp Pollen Extract Arlco.

I prepared by the method given for pollen extracts Arlco (New and Nonofficial Remedies 1930, p. 29)

REPORTS OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS

W. A. PUCKNER, Secretary

PERTUSSIS VACCINES OMITTED FROM N N R

Pertussis bacillus vaccine was admitted to New and Nonofficial Remedies in 1914 on the basis of what appeared to be acceptable clinical evidence. In 1915 the following statement appeared in New and Nonofficial Remedies under the head of pertussis bacillus vaccine. The evidence indicates that it is of value both for prevention and treatment although eminent authorities state that the results have not been very satisfactory. In subsequent years when vaccine therapy was at its height pertussis bacillus vaccine was used extensively and yet critically controlled reports did not become available. In the light of this lack of confirmatory evidence the Council revised its statement to indicate a more skeptical attitude toward the product. Acceptable confirmatory reports still being lacking in 1928 the Council voted to omit pertussis vaccines with the close of

the longest period for which any one was accepted, unless in the meantime acceptable evidence for its usefulness in the prevention or treatment of whooping cough became available.

With the approach of the expiration of the stipulated period, the Council's referee in charge of the product reviewed the present evidence. Since in 1928 a clinical member of the Council had stated that he used pertussis vaccine in his practice, he was consulted in regard to his present estimate of the usefulness of the product. He reported that so far as he could learn from pediatricians and from consultation of the literature there is a general impression, difficult of absolute proof, that freshly prepared pertussis vaccines given during the period of incubation may be of value in modifying attacks and reducing the mortality of children and infants in whooping cough. As a preventive, he states that pertussis vaccines seem to have absolutely no influence and after the disease is thoroughly established even freshly prepared vaccines seem useless. He reports no evidence even for the presumptive value of stock or commercial vaccines.

In view of the fact that in fifteen years of extensive use no acceptable confirmatory evidence for the value of pertussis bacillus vaccines has become available, the Council voted to confirm its decision to omit from New and Nonofficial Remedies the accepted products, as follows: Whooping Cough Vaccine X Plim (Cook Laboratories, Inc.), Special Pertussis Vaccine (The Cutter Laboratory), Pertussis Bacillus Vaccine (The Gilliland Laboratories, Inc.), Pertussis Bacillus Vaccine (Hollister Stier Laboratories), Pertussis Glycerol-Vaccine Lederle Pertussis Vaccine for Prophylaxis (Lederle Laboratories, Inc.), Pertussis Vaccine for Treatment (Lederle Laboratories, Inc.), Pertussis Vaccine (Eli Lilly & Co.), Pertussis Bacterin Mulford Pertussis Vaccine (The National Drug Co.), Pertussis Vaccine (Parke, Davis & Co.) Pertussis Immunogen (Parke, Davis & Co.), Pertussis Vaccine, Immunizing (E. R. Squibb & Sons) Pertussis Vaccine, Curative (E. R. Squibb & Sons), Pertussis Bacterin-Swan Myers (Prophylactic).

THROMBOPLASTIN HYPODERMIC-SQUIBB OMITTED FROM N N R

Thromboplastin Hypodermic-Squibb (E. R. Squibb & Sons) is a sterilized extract of cattle brain in physiologic solution of sodium chloride intended for hypodermic injection to increase the coagulability of the blood. It was accepted by the Council for inclusion in New and Nonofficial Remedies as a brand of solution of brain extract (New and Nonofficial Remedies, 1930, p. 183). The Council first accepted thromboplastic substances in 1915. Since then little or no additional evidence has developed for the value of these preparations; their intravenous use almost certainly presents dangers and the Council has become convinced that there is no satisfactory evidence for their effectiveness when injected subcutaneously. In view of this the Council decided unless new evidence should appear not to include hereafter in New and Nonofficial Remedies any preparation of this type except for local application.

Since Thromboplastin Hypodermic Squibb is intended for hypodermic or subcutaneous injection E. R. Squibb & Sons were informed of the action of the Council and asked to submit evidence in support of the value of the hypodermic administration of thromboplastic substance. The firm replied that after a thorough search of the literature on Thromboplastin Squibb from 1923 to 1929 only two articles dealing directly with the preparation had been found; that there were many reports concerning the therapeutic action and uses of other tissue extracts of similar properties. The firm enclosed abstracts of two articles dealing with Thromboplastin Squibb and abstracts of thirty-two articles dealing with other similar tissue extracts. The submitted evidence did not permit a revision of the Council's conclusion that the hypodermic or subcutaneous administration of Thromboplastin Hypodermic Squibb or of other thromboplastic substances is not therapeutically valuable. As with other reports concerning the use of blood coagulants the submitted articles are inconclusive and unconvincing.

Because of the lack of evidence for the therapeutic value of subcutaneous or hypodermic administration of Thromboplastin Hypodermic Squibb or of other thromboplastic substance the Council voted to omit Thromboplastin Hypodermic Squibb at the expiration of the period for which it was accepted.

THE INCREASING PREVALENCE OF PELLAGRA

Recent reports by the U S Public Health Service indicate that the prevalence of pellagra has been increasing for several years in this country The progress in the study of the disease, the newer insight into its probable etiology, and the vaunted prophylactic as well as curative measures applicable to the malady have awakened the hope that uncertainty is about to be replaced by confidence in its management Yet government records¹ recently submitted to Congress contained the ominous information that the pellagra death rate computed in 1924 as 2.5 in each hundred thousand of population rose steadily to 5.7 in 1928 and that in 1929 it was 5.5

Pellagra is not a new disease, though its prevalence in the United States was not appreciated until the present century In most countries it has been regarded as an essentially chronic malady confined almost entirely to the poorer classes in rural communities, but this has not been equally true in the United States, where it has been found to affect both the white and the Negro races Pellagra was described nearly two centuries ago, as early as 1735, under the designation of *mal de la rosa*, but the present appellation (*pelle agra*, rough skin) dates from Francesco Frapolli's description in 1771 A hospital was early established in Milan for the treatment of the disease, a three-volume treatise, *De Pellagra*, being published during the years 1786 to 1789²

Several theories regarding the cause of pellagra have been propounded The oldest—the zeist hypothesis—attributed the disorder to the use of spoiled corn, as it occurred conspicuously among maize-eating groups Subsequently pellagra was classed by many in the category of infectious diseases due to a specific micro-organism There was much in its incidence to suggest a microbiotic etiology, but the latter has been abandoned largely because of the pioneer investigations of Gold-

berger and his associates in the Public Health Service They have insisted on a dietary origin for pellagra placing it in the category of so-called deficiency diseases Pellagra does not occur in persons who regularly consume a well ordered mixed diet The sufferers are likely to have subsisted on a regimen in which the protein content was low and of poor biologic quality, with a paucity of fruits and green vegetables Goldberger believed that he had found an analogue of human pellagra in the so-called black tongue of dogs This, like pellagra, yields to corrective dietary measures

Recently, and again through Goldberger's leadership attention has been called to the effect of vitamin deficiencies in provoking the appearance of pellagroid symptoms The existence of a pellagra-preventing vitamin, designated successively as P-p, B, and G according to current usage, has been postulated This is part of the vitamin mixture formerly designated as water-soluble B It has become possible to separate products such as yeast, rich in the vitamin B "complex" into parts, of which one is conspicuously antineuritic and another protective against a form of dermatitis that arises, in experimental animals, in its absence Milk, meat and yeast are relatively rich in vitamin G, in which the cereal grains are poor On such considerations, prophylactic measures have been based

A somewhat different hypothesis has just been formulated by Bliss³ at the Tulane University of Louisiana School of Medicine, who ventures the suggestion that pellagra is in reality an iron-deficiency disease He points to anemia as a frequent concomitant of pellagra He also notes that the foods which are supposed to contain liberal quantities of vitamin G (beef, liver, egg yolk, yeast) are all iron-containing foods (some of them being among those containing more iron than any other known biologic product), while the pellagra-producing diet of poor farmers of the South (molasses and corn bread) is extremely poor in iron Bliss reports results of "a very encouraging nature" from iron therapy with pellagra patients In severe cases the iron was administered intravenously, and in milder cases it was given orally Animal experiments also were encouraging It would, of course, be extremely premature to endow these observations with the dignity of proof, but many clinical students of pellagra still believe that the last word regarding the nature of the disorder has not been spoken There are, indeed, reasons for assuming that pellagra as seen in man represents a syndrome—a group of symptoms including stomatologic, gastro-enteric, cutaneous and nervous manifestations, each of which may have independent pathogenic origin The hypothesis of multiple deficiencies with consequent protein disease characteristics is somewhat appealing It has again become "open season" in the hunt for explanations The most recent morbidity statistics encourage a vigorous pursuit

THE PREMATURE CHILD

Recent years have witnessed an increasing consideration of the problem of the prematurely born child. The postpartum care has been greatly improved with respect to incubator facilities, the heating and ventilation of the environment, diet and nursing care. From the point of view of physical equipment and hygienic care, real progress is to be anticipated. There are, however, many records that promote discouragement in the contemplation of the effect of premature birth on the subsequent growth and development of the child. For example, in an elaborate review of the subject based on a study at the Children's Clinic of the University of Vienna, Capper¹ wrote in 1927:

The fate of immature children is not enviable: almost one half of them die during the first year of life. Of those that remain alive, the majority are physically as well as mentally underdeveloped. Some of them show a late mental development, others show a condition of psychic infantilism if the term may be used in its nonspecific sense, while still others show permanent and severe mental diseases. When they are passed in review, one is surprised at the variety and amount of abnormality encountered almost a regular "pathologic museum." In brief, the immature infant becomes the backward school child and is a potential psychopathic or neuropathic patient and even a potential candidate for the home for imbeciles and idiots.

Fortunately, this disheartening conclusion may be offset by the psychologic investigation recently completed in the Sarah Morris Hospital for Children, Chicago, by Mohr and Barthelme.² The care of their prematurely born patients had evidently been superior. The data regarding their physical development need not be reviewed here.³ A comparison of performances of fifty individual prematurely born children with those of their forty full term siblings, on the basis of the relation of mental age to chronological age in each case, revealed no significant difference in the mental development of the two groups, if due allowance was made for the period of prematurity. The prematurely born children did not differ from full term children in the time of the beginning of eruption of teeth, in onset of walking, in beginning of talking and in the learning of bladder control, if correction was made for the period of prematurity. The smaller prematurely born children were consistently a little later in these developments, but again the difference was minimized if this correction was made. Furthermore, in "personal-social behavior" the performance of the prematurely born children was consistently relatively superior. This may be attributable to the unusual care and attention offered prematurely born children or to their additional opportunities for social experience. In motor performances the children were relatively poor. Those who weighed relatively more at birth tended to do better on the tests for mental development. Of course it would be absurd to dis-

regard the hazard that premature birth presents. The Chicago records were by no means devoid of unfortunate cases. According to Mohr and Barthelme, hemorrhage and other injury at birth result in consequences to prematurely born children that do not differ from those clinically noted among the children born at full term. If they occur more frequently among the prematurely born, they constitute an extra hazard of prematurity. The important feature of this behavior research is its optimistic outlook. Its implication is that adequate opportunities must be provided for the care of those who are handicapped by premature birth.

BIOCHEMISTRY IN THE UNITED STATES

Physiologic chemistry—or biochemistry, as it has been commonly designated more recently—has long since come of age. The subject has become an important and integral part of the study of medicine and the practice of the art. The special technique of biochemistry has been introduced into clinical diagnosis to such an extent that it competes in prominence with physical procedures and with bacteriologic and immunologic methods of examination and research. A recent writer¹ has remarked that today it is quite safe to state that in the United States there is hardly a university worthy of the name that does not have on its staff one or more competent investigators in physiologic chemistry and a well equipped laboratory with resources adequate for at least some lines of research in this field. Added to these centers of research are the many special laboratories connected with the larger hospitals of the country where investigations of a chemiophysiology character are conducted, the many research institutions and foundations with their large endowments, where many biochemists of national reputation are to be found, and, lastly, the various government bureaus at Washington with their well equipped laboratories and trained workers who have contributed largely to the development of knowledge of a chemiophysiology nature in many directions.

Despite this current situation there was a time in this country, within the recollection of physicians still living, when an American student desirous of making progress in physiologic chemistry had no recourse other than going to Germany for the knowledge and experience he needed to help him on his way. He might be well trained in chemistry according to the standards of that date but he would be wholly lacking in the knowledge of methods, in the proper way of approach, for the study of physiologic problems. In an elucidating review of the development of physiologic chemistry in the United States Prof. Russell H. Chittenden, the dean of living American biochemists, points out that the first definitive laboratory of physiologic chemistry in America for the instruction of

students was established in the Sheffield Scientific School at Yale University in 1874, under his charge.

Less than sixty years has brought a degree of progress far beyond the dreams of the most ardent enthusiasts of the latter part of the nineteenth century. Forty-three years ago (Dec. 30, 1887) occurred the organization of the American Physiological Society which took under its wing most of the professional biochemists of that period. The society now numbers more than 400 members and controls its own professional journal. In a few months the American Society of Biological Chemists, which also publishes a research journal, will celebrate its quarter-centennial. It was organized in 1906 to relieve the pressure in the parent society, with the purpose "to further the extension of biochemical knowledge and to facilitate personal intercourse between American investigators in biological chemistry." The entire development of this fundamental prerequisite of medical progress still partakes of the characteristics of youth with all its potencies for development. Little wonder that Cluttennden has concluded that "there would seem to be good ground for the belief that the future of physiological chemistry in this country is full of promise, and that what has been accomplished is but the forerunner of more nearly perfect knowledge."

Current Comment

LOSS OF PANCREATIC JUICE AND ACID-BASE BALANCE

The pancreatic juice is a digestive fluid of major importance. In connection with the succus entericus and the bile it exerts a powerful hydrolytic effect on fats, carbohydrates and proteins. In contrast to the gastric juice, the external secretion of the pancreas is definitely alkaline, containing about 0.5 per cent of sodium carbonate. When the ducts are cannulated and the secretion led to the outside, serious digestive difficulties result. However, the fatal consequences are probably due not to the removal of the digestive enzymes alone but, in no inconsiderable degree, to concomitant loss of inorganic ions from the body, notably fixed base. Recent studies on animals by Dragstedt¹ show that loss of pancreatic juice is accompanied by changes in the composition of the blood that indicate a condition of acidosis. For the first five days after the pancreatic fistula had been established, large volumes of Ringer's solution were given intravenously and the animal was in good condition. Weakness and depression promptly occurred on discontinuance of the injections, and death occurred in from four to six days. There was a decrease in plasma base, in chloride and in bicarbonate, and the concentration of hydrogen ions increased. At the same time the urea in the blood increased. These evidences of loss of base in the pancreatic juice under the conditions of the experiment

emphasize the usual reabsorption of base from the intestine and recall the importance of the internal circulation of compounds in the body. Former studies by Dragstedt and Ellis² on the fatal effect of complete loss of gastric juice and the remedial influence of sodium chloride solution show that the chloride secreted in gastric juice also is absorbed again into the blood. It is believed that iron is subject to a similar reabsorption, while after secretion by the liver the bile salts pass into the blood stream again with the fatty acids. Substances that play an important part in physiologic economy and that must be provided preformed in the food are not likely to be wasted by the body under ordinary conditions.

NEW YORK REGULATES BLOOD DONORS

The department of health of New York City has adopted codes and regulations governing blood donors. These regulations provide for the registration and supervision of blood donors according to definite rules. A "blood donor" means "any person who holds himself out as willing to dispose of his blood, or who offers his blood, or whose blood is used for transfusion purposes, for a fee." No person can act as a blood donor in the sense just indicated without a certificate of registration from the department of health. This certificate is good for one year only. The applicant for registration must furnish the report on an official form by a licensed physician, giving the results of a competent physical examination made not longer than seven days before the application is presented. No person may be registered who is below standard in weight, whose blood is not negative on the Wassermann or the Kahn test, who has a positive syphilitic history or who exhibits suspicious scars or symptoms of syphilis or who gives a history of malarial infection or who presents evidence of any disease of the heart, hyperthyroidism, asthma, status lymphaticus, tuberculosis, venereal disease or any communicable disease or evidence of drug addiction, whose blood group has not been determined, or who has been found to be a "dangerous universal donor." Every certified donor must keep a personal record book furnished him by the department of health, with personal description, photograph, signature, blood group, reports of physical and other examinations, and the transfusions in which he acts as donor. Not more than three weeks can elapse between his giving blood in transfusion and a new physical examination, the results of which are to be recorded in his blood donor's registration book. "No blood donor shall be accepted whose hemoglobin is found to be less than 85 per cent of the normal for the method employed." Again, no donor shall be used whose blood has not been found to be negative to standard tests for syphilis by the department of health within six months before a transfusion. By this test and by the repeated physical examinations, syphilitic infection since certification should be detected. Finally, immediately prior to transfusion, the physician in charge must examine the donor to determine whether he is in a normal state at that time. The regulations provide

¹ Dragstedt L. R. Montgomery M. I. Mathews W. B. and Ellis J. C. *Proc. Soc. Exper. Biol. & Med.* 28: 110 (Nov.) 1930.

² Dragstedt L. R. and Ellis J. C. *Am. J. Physiol.* 92: 407 (June) 1930.

also for full records and reports of transfusions by physicians and hospitals, which are transmitted to the department of health or, in the case of certain hospitals, are always accessible to its inspectors. While "no transfusion shall be made unless from a registered blood donor," it is provided that "in the case of an emergency a husband or wife, a parent or child or a relative or friend may be used as blood donor." The certificate of registration is revocable in case the donor contravenes any regulation or gives indications of syphilitic, tuberculous, malarial, typhoid or any other communicable infection or of having given too much blood. Agencies for blood donors may not be maintained without permit from the department of health and may not employ any other than certified donors. It is evident that the New York regulations have been worked out with great care under expert advice, both scientific and administrative. The regulations aim by careful and repeated examinations and tests to exclude unsuitable persons from acting as blood donors. Obviously this object cannot be attained fully without the willing cooperation of physicians and hospitals. This is said to be the first official regulation of blood donors, and they will serve as models for other efforts in the same direction. The number of persons offering to sell their blood appears to be increasing, especially of late on account of unemployment, and the best interest of the patient and the public requires more careful, more systematic supervision of blood donors than at present. The health department of New York is to be congratulated on having taken such an important step toward proper regulation.

Association News

MEDICAL BROADCAST FOR THE WEEK

American Medical Association Health Hints

The American Medical Association broadcasts at 10 a m on Monday, 10 45 on Tuesday, 10 45 on Thursday and 10 o'clock on Saturday, over Station WBBM (770 kilocycles or 389 4 meters).

The program for the week is as follows:

February 23 We Need Pure Air
February 24 If Your Child Is Hurt
February 26 Home or Sanatorium for Care of the Tuberculous
February 28 Use Your Doctor As a Health Guide

Five minute health talks may be heard over the Columbia Broadcasting System daily except Sundays and Holidays from 12 to 12 05 p m.

The program for the week is as follows:

February 23 The Mechanics of Smell
February 24 What People Believe
February 25 Alchemy
February 26 Height and Weight
February 27 Man's Marvelous Machinery
February 28 The Caduceus

THE PHILADELPHIA SESSION

Special Exhibit on Varicose Veins in the Scientific Exhibit

The Committee on Scientific Exhibit of the Board of Trustees has decided to continue the special exhibit dealing with the treatment of varicose vein including the injection method. The following have been appointed as members of the committee: Geza de Zarkov MD, chairman, Chicago; Claude I. Dixon MD, Rochester, Minn.; and Howard M. Kern MD, Baltimore. In addition there has been appointed an advisory committee consisting of George E. Brown MD, Rochester,

Minn.; John Homans MD, Boston; George P. Muller MD, Philadelphia; Walter B. Sistrunk MD, Dallas, Texas; and H. H. Trout MD, Roanoke, Va.

The committee plans to present in the form of charts the indications and contraindications of injection treatment, the type of solutions used, the possible errors in technique, untoward symptoms during and after treatment, dangers, and end-results. The combination of injections with ligation of the saphenous vein and the radical excision of veins will receive consideration, especial emphasis will be given to the prevention and treatment of necrosis following injection treatment and on the conservative and surgical treatment of chronic ulcers of the leg.

In addition, arrangements will be made for the demonstrations on patients in small groups, as this part of the exhibit created so much interest last year. The tables shown in the exhibit will be compiled in pamphlet form and given out at the exhibit to visiting physicians.

CONTRIBUTIONS FOR MEDICAL SALON IN PERSHING HALL

The sum contributed this week for the Pershing memorial in Paris brings the total to \$1,884 60. A list of those who have contributed during the current week follows:

Col. Thomas J. Burrage Portland

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

ARIZONA

Bills Introduced—S 53 proposes to create a board of orthodontic examiners and to regulate the practice of orthodontia. H 122 proposes to authorize counties, or combinations thereof, to establish and maintain general hospitals. H 133 to amend that portion of the medical practice act which states to what persons the act shall not apply, proposes that 'nothing in this chapter shall inhibit service in an emergency, or the domestic administration of family remedies or the practice of religion or treatment by prayer nor shall it apply to any commissioned medical officer in the United States Army Navy or Public Health Service, in the discharge of his official duties nor to any licensed practitioner from another state when in actual consultation with a licensed practitioner of this state.'

ARKANSAS

Bill Introduced—S 135, if enacted, would apparently exempt chiropractors from the provisions of the basic science act and would make the board of chiropractic examiners the sole judge of the eligibility of all applicants for a license to practice chiropractic.

CALIFORNIA

Bills Introduced—S 409 proposes to raise to \$5 the annual fee which licensed dentists are required to pay the board of dental examiners. A 477 proposes to create a state medical library in the state library at Sacramento.

John P. Shepherd Fined for Illegal Practice—John P. Shepherd, Santa Rosa, is said to have pleaded guilty through his attorney, recently, to a charge of violating the medical practice act, and agreed that no further advertising would appear showing his name prefixed by the letters 'Dr.' or in any way indicate that he was conducting any form of practice. He is said to have paid a fine of \$100. Shepherd's name appeared in the city telephone directory with the prefix 'Dr.' and in the classified section under the heading 'Physicians and Surgeons'—M.D. Hillside Sanitarium. It was alleged further that he professed to treat tuberculosis. Shepherd is said to have applied for a license to practice in Indiana, June 4, 1897, stating in his affidavit that he had been engaged in the practice of medicine, surgery and obstetrics in Fountain, Mellott County, since December, 1896, and claiming that he had been a practitioner in the state for eleven years preceding the date of the affidavit. Records of the Indiana State Board of Medical Registration and Examination indicate that Shepherd was licensed under a clause in the medical law of 1897 which provided for licensure of all persons who had been engaged in the practice of medicine in Indiana for ten years prior to the passage of the act of 1897. No diploma or evidence of graduation was required of those furnishing a record of ten years practice. Shepherd seems to have claimed to have graduated from the University of Toronto Medical Faculty in 1886. When he was interviewed by a special agent of the California board in January, 1930 he is said to have claimed to be a graduate of Jefferson Medical College. The records of the American Medical Association fail to show that Shepherd is a graduate of either Toronto or Jefferson, or of any other reputable institution.

COLORADO

Bill Introduced—H 169 proposes to create a board of chiropractic examiners and to regulate the practice of chiropractic authorizing such practitioners to practice chiropractic as taught in chiropractic schools and colleges and to use the titles Doctor or Dr. in connection with their names when accompanied by the word Chiropractor or the letters D.C.

CONNECTICUT

Bills Introduced—S 31 proposes to amend the law with respect to the manner in which the board of examiners of midwives is selected by giving the governor the power to appoint the board. H 976 to amend the pharmacy practice act proposes to authorize the board of pharmacy to issue per-

mits to general dealers to sell proprietary medicinal compounds or preparations put up separately in sealed packages by licensed pharmacists. However, nothing herein contained shall authorize such permittees to sell any compound containing among other things, neonal, amyral, dial, or any preparation containing barbituric acid. S 215 to amend the law requiring physicians to report cases of certain industrial poisonings, seeks to provide that information obtained on investigation made as a result of the report shall not be admissible as evidence in any action at law or of the workmen's compensation act. S 333 proposes to exempt from the law requiring the licensing of all private hospitals any institution operated or maintained by any religious or fraternal organization having a board of managers or directors. H 156 would if enacted, permit licensed physicians to give contraceptive information and advice to patients.

Coordination of Medicine and Dentistry at Yale—Dr. Milton C. Winternitz, dean Yale University School of Medicine, discussed the school's plan to promote the integration of dentistry and medicine February 4, before the New Haven Dental Association. There are now four graduate dentists taking the regular course in medicine at Yale, and each year two such dentists are to be admitted, so that eventually there will be at all times eight dentists taking the course. B. G. Anderson, D.D.S., formerly associated with the University of Minnesota, Columbia University and Peiping Union Medical College as dental surgeon, has been appointed to head the clinical activities in dentistry at Yale. He will be in charge of the dental suite in which dental work for ambulatory and hospital patients unable to pay will be conducted. An investigation supported by the Rockefeller Foundation, is being made of the teeth and bacteria found at their roots in relation to both acute and chronic diseases. An endeavor is being made to discover why extraction of the teeth often alleviates diseases of the joints, heart, kidneys and eyes and to determine the significance of devitalized teeth of bacteria associated with them and of the destruction of the tissues forming the bed of the tooth. The plan it is hoped will create a liaison group which will draw physicians and dentists together to their mutual advantage.

DELAWARE

Bills Introduced—H 90 proposes to create a board of chiropractic examiners and to regulate the practice of chiropractic, defined as 'a drugless health system the basic principle of which teaches that disease is caused by interference with the transmission of nerve impulses. The diagnosis the location of misaligned or displaced vertebrae of the human spinal column, the procedure preparatory to and the adjustment by hand of such misaligned or displaced vertebrae of the spinal column and its articulations, by any method not including the use of drugs, surgery or obstetrics nor any branch of medicine, nor osteopathy for the purpose of relieving such interference.' S 43 to amend the law regulating graduate nurses proposes (1) to authorize the board of nurse examiners to formulate a curriculum and rules to be complied with by training schools and hospitals desiring to be accredited by said board, and (2) to require applicants for licenses to have had at least one year of high school work prior to their nursing education. After Jan. 1, 1934, all applicants must have four years of high school work.

GEORGIA

Dr. Copanaris Honored—Dr. P. Copanaris, director of hygiene of the Republic of Greece was tendered a banquet by the city of Savannah February 3. Dr. Copanaris has been visiting health departments in America as the guest of the International Health Division of the Rockefeller Foundation.

Midwives in Georgia—Four thousand midwives were practicing in Georgia at the beginning of this year, the state board of health reports. During the past year nurses of the state board of health gave instruction to 3,729 midwives. It is said that one third of the births in the state are attended by these women and that more than 20,000 babies born each year in Georgia are unattended by a physician.

No Fatality from Smallpox—According to the state department of health, the 1930 death rate showed a decrease of 1.6 per cent from the rate for 1929. Twenty one causes of death contributed most to the number of deaths reported eleven showing decreases from 1929 while ten showed increases. Among those showing decreases are accidents, diphtheria, influenza, malaria, nephritis, pellagra, scarlet fever and smallpox, and those showing increases cancer, cerebral hemorrhage, diabetes, diarrhea and enteritis under two years, dysentery and

heart disease. The greatest decrease was in smallpox, which, for the first time in many years, failed to show a death, and the greatest increase was in measles which showed a death rate 3097 per cent higher than in 1929.

ILLINOIS

Bills Introduced—H 192 proposes to provide that, in distributing funds of an estate, expenses attending last illness, including physician's bill, funeral expenses and necessary costs of administration, shall have priority over all other claims against the estate. S 68 proposes to authorize the governing board or council of cities, villages, counties and schools to employ public nurses. Such nurses must be licensed by the department of registration and education.

Chicago

Rare Publications—A copy of volume I of the *Medical Repository* which appeared in 1798 and which was the first American medical journal, is among the exhibits at the library of the University of Illinois College of Medicine in a display of early medical Americana. There is also a collection of the writings of Benjamin Rush, an autographed copy of a work by Marion Sims, and a copy of the first medical dictionary compiled by an American and Beaumont's book on digestion. Photographs of men famous in the medical history of the United States are also included.

Personal—Dr Henry Schmitz, professor of gynecology, Lovola School of Medicine received the gold medal of the Radiological Society of North America for 1930 for achievement in the science of radiology in its application to diseases of women.—Dr Harry C. Rohnick was appointed February 4, as consulting urologic surgeon for the Illinois State Industrial Commission.—The showing of three motion pictures with sound took place, February 11, at St. Luke's Hospital, the pictures are the work of Dr. Harold O. Jones, associate professor of obstetrics and gynecology, Northwestern University Medical School. The titles are "Suspension of the Uterus for Retrodisplacement", "Salpingectomy and High Femoral Amputation for Residues of Tubal Disease," and "Vaginal Hysterectomy for Uterine Prolapse."

INDIANA

Bill Introduced—H 342 proposes to make it unlawful to sell or supply any food drink, medicine or toilet preparation intended for human use or any antifreeze agent for motor vehicle radiators, containing wood alcohol, methanol or methyl alcohol. All sales must be made in containers labeled "deadly poison—wood alcohol."

Society News—Dr. Leroy W. Hubbard, Warm Springs, Gr., will address the Indianapolis Medical Society, February 24, on "Development of Warm Springs Foundation for the Treatment of Paralysis Due to Poliomyelitis."—Albert Stump, LL.D., Indianapolis, addressed the Tippecanoe County Medical Society, La Fayette, February 12, on "Special Legal Rights and Duties of Professional Men."—Dr. Louis E. Phaneuf, Boston, addressed the February 12 meeting of the Indianapolis Academy of Medicine and Surgery on "Transverse Cervical Cesarean Section."

IOWA

Bills Introduced—H 128 proposes to record liens to hospitals, physicians and nurses treating persons injured in accidents on any settlements or judgments obtained by the injured persons by reason of the accidents. H 149 proposes to require every professional licensee to keep his license publicly displayed in the place in which he practices. H 150 proposes to require pharmacists to inform purchasers of certain designated poisons of the character of the poison and to ascertain that the drugs are to be lawfully used. H 159 to amend the pharmacy act proposes (1) that those who manufacture drugs, poisons or medicines for sale at either wholesale or retail shall be deemed to be engaged in the practice of pharmacy, (2) to define a pharmacy as a drug store in which the prescriptions of licensed physicians, surgeons, dentists or veterinarians are compounded and sold by a registered pharmacist or where drugs, medicines or poisons are exposed or sold at retail, (3) to prohibit all persons from allowing any one who is not a licensed pharmacist to sell or dispense any drugs, poisons or medicines, unless it is done under the immediate personal supervision of a licensed pharmacist, and (4) to prohibit a registered pharmacist from allowing his certificate as a licensed phar-

macist to remain in or on display at any place of business unless he is legally employed there. H 174 and S 110 propose to amend the osteopathic practice act by authorizing osteopaths to prescribe or dispense internal curative medicines and by designating osteopaths as "physicians." H 129, to amend the law requiring the reporting of venereal diseases to local boards of health by physicians, proposes to require physicians to make such reports to the state department of health except when cases occur in the jurisdiction of full time municipal or county health officers, when such reports shall be sent to such officers. H 155 proposes to exempt tools, instruments and books of dentists from execution. H 224 proposes (1) to permit the state department of health to refuse to renew a license to practice medicine, on any of the grounds for which a license may be revoked by the district court, and (2) to permit a practitioner whose license has been revoked, either by action of the department of health in refusing to renew the license or by the district court, to have his license renewed by order of the state board of health on recommendation of the commissioner of health. H 223, to amend the medical practice act proposes that any person doing anything that under the statute constitutes the practice of medicine shall be deemed to be practicing medicine even though he is acting only as the representative of someone else. H 225 proposes to permit osteopaths to use the prefix "Doctor" if followed by the letters "D O" or "O S," and chiropractors to use the prefix "Doctor" if the letters "D C" follow the name. Even optometrists are allowed to use the title provided the letters "Opt" or "Optometrist" follow the name.

KANSAS

Bill Introduced—H 315 proposes to authorize the governing body of any city of the second or third class, owning and operating its own light and water plant, to furnish water, electric light and power to any hospital within the corporate limits of such city, free of charge, or at such reduced rates as the governing body may set.

MAINE

Bills Introduced—S 250 proposes to authorize the sterilization of certain socially inadequate inmates of state institutions. H 340 proposes to create a board of examiners of chiropodists and to regulate the practice of chiropody, defined as the treatment medically, mechanically, or surgically of the ailments of the human foot without the use of anesthetics other than local. H 408 proposes to create a state department of hospital aid, to consist of the commissioners of the department of public welfare ex officio, to provide medical and surgical treatments for persons whose resources are insufficient to pay for such treatments.

MASSACHUSETTS

Personal—Dr. George W. Gale who is 94 years old is planning to retire as a member of the Saugus Board of Health when his term expires in March after nearly thirty five years service.—Dr. Stephen Rushmore has been appointed a member of the board of registration in medicine to succeed Dr. Horace D. Arnold, resigned.—Dr. Frederick Carpenter Irving has been appointed professor of obstetrics at Harvard University Medical School, effective September 1.

Bills Introduced—H 83 proposes to direct the department of public health to formulate a plan for the care and treatment of persons suffering from rheumatism and allied chronic conditions. H 781 proposes to create a board of examination and registration for magnetic healers and to regulate the practice of magnetic healing. No educational requirements whatsoever are set forth in the bill nor is there any mention of what the examination will consist other than that it includes the subject of nerves. H 914 proposes to regulate the practice of chiropody therein defined to be the method, science or practice of locating and adjusting the subluxations of the articulations of the human spine and its adjacent tissues. No chiropactor shall unless registered as a physician or surgeon, practice obstetrics, or administer drugs or perform surgical operations by the use of instruments nor shall treat, unless under the directions of a physician, eruptive, erosive or temperative disturbances coming under the accepted definitions of contagious, infectious or reportable diseases. H 977 proposes (1) to require the consent of a patient before a physician may remove any organ of the body and after removal to require the physician to explain to the patient the necessity for such removal, (2) to extend to six years the statute of limitations on actions on contract or tort for malpractice, negligence, error

or mistake against physicians, (3) to provide that a physician shall not handle a patient in such a way as to cause pain without first explaining that pain will result from such handling and obtaining permission therefor from the patient. H 1069 proposes to provide a penalty for any person who shall be convicted of obtaining medical or surgical treatment from any dispensary on false representations as to his place of residence or as to his pecuniary circumstances.

MICHIGAN

Bill Introduced—H 88 proposes that, subject to the approval of the board of supervisors, a county health department shall have the power to employ such physicians and nurses, full or part time, as shall be necessary to carry out its work.

Professors Appointed—Dr Norman F Miller, professor of obstetrics and gynecology at the State University of Iowa School of Medicine, Iowa City, since 1926 has been named professor of obstetrics and gynecology and Bates professor of diseases of women and children at the University of Michigan Medical School Ann Arbor to succeed Dr Reuben Peterson, resigned. Dr Fred Jenner Hodges lecturer in radiology University of Wisconsin Medical School Madison was appointed professor of roentgenology to succeed the late Dr Preston M Hickey.

MINNESOTA

Bills Introduced—S 376 proposes to make it permissive for boards of education to establish physical and health education in the schools under their jurisdiction. Apparently, the present law makes the establishment of these courses mandatory. S 436 authorizes cities of the fourth class to establish and maintain city hospitals. H 406, if enacted would apparently, repeal the provision of the pharmacy act that allows any general dealer whose shop is more than 2 miles from a drug store to sell any commonly used medicine or poison which has been put up for such use by a registered pharmacist.

Medical Journal Celebrates Sixtieth Anniversary—The *Journal-Lancet* which represents the medical profession of Minnesota North Dakota, South Dakota and Montana, celebrates its sixtieth anniversary with the February 1 issue. The jubilee number contains, in addition to scientific papers articles on "The Future of Medicine in the Northwest," "The Development of Preventive Medicine in the Northwest," "Development and Progress of Pediatrics in the Northwest," "Early History of the Hennepin County Medical Society," and histories of the North and South Dakota state medical associations.

Violations of Basic Science Law—Averhino Fernandez, formerly of Monterey, Mexico, was sentenced to one year in the workhouse at St Paul, January 12, following his plea of guilty to a charge of practicing healing without a basic science certificate, according to the state board of medical examiners. Fernandez had been in St Paul about sixty days at the time of his arrest. He had had no medical experience but said he had worked in a drug store in Monterey. His practice was confined to Mexicans in St Paul.—John Hugh Lally operated an office at the St Paul Hotel, St Paul, during the month of November, 1930, and departed rather hastily from the state after the state board of medical examiners instituted an investigation of his activities. He was found guilty at Winnipeg, January 9 of treating persons contrary to the provisions of the Medical Act of Manitoba, Canada and fined \$100 and costs. The Minnesota board cooperated with the Manitoba authorities.

MISSOURI

Bill Introduced—H 302 proposes to provide that no form of vaccination or inoculation shall hereafter be made a condition precedent for the admission of any person to any public school college or university or for the exercise by any person of any right, the performance of any duty or the enjoyment of any privilege.

MONTANA

Bill Introduced—H 254 proposes to amend the workmen's compensation act by (1) providing that the term "physician" as used in the act shall include practitioners of chiropractic and (2) providing that where an injured employee is under a hospital contract and the hospital or medical facilities accorded are insufficient for the case the injured employee may at any time be placed where adequate hospital facilities are obtainable and the cost thereof shall be a legal charge against the one contracting to furnish hospital facilities.

NEBRASKA

Bills Introduced—H 220 proposes to regulate the practice of cosmetology. H 280 proposes that in counties having no regularly appointed physician or where it is necessary for the county board to employ other physicians to render public medical aid to the poor, such physicians so employed shall receive, as compensation, 50 per cent of the prevailing charge for similar services in such counties.

Society News—The Custer County Medical Society was addressed, Dec 11, 1930, by Drs Theodore H Koefoot, Broken Bow, on "Albuminuria" and Roy D Bryson Callaway, "Injection Treatment of Varicose Veins."—Drs Robert B Eldredge, Abram E Bennett and Willis H Taylor, Omaha, spoke on vaccines, serum treatment of infantile paralysis and modern obstetric procedures, respectively, before a recent meeting of the Cass County Medical Society, Weeping Water.—A symposium on anterior poliomyelitis was conducted before the Cedar, Dakota, Dixon, Thurston and Wayne Counties Medical Society, Wakefield, Nov 20, 1930 the speakers were Drs Allen C Sturtevant, Robert H McBride, Archibald F O'Donoghue and William D Rumon, all of Sioux City, Iowa.—Drs William P Wherry and Arthur D Dunn addressed the Omaha Douglas County Medical Society, January 27, on "Chronic Hyperplastic Mastitis Simulans and Its Relation to General Medicine." Dr Mame C Andersen spoke on "Ventricular Paroxysmal Tachycardia." Drs Rollin Russell Best, Omaha and Weaver A Rush, Beatrice, addressed the society, February 10 on "Operative and Nonoperative Treatment of Peptic Ulcers" and "Teeth Medically and Radiologically Considered" respectively.

NEW HAMPSHIRE

Bills Introduced—H 114 proposes to include cosmetics the list of substances covered by the state pure food and drug law. H 115 proposes to amend the pharmacy practice act (1) making it the duty of the state board of health to cooperate with the state board of pharmacy in analyzing samples of drugs sold in violation of the act, (2) making it unlawful for any person not a registered pharmacist or an assistant pharmacist in a drug store registered in accordance with the provisions of the act, to compound, dispense, or sell any potent drug and (3) permitting the general sale of proprietary medicines except proprietary medicines containing acetylsalicylic acid, barbitol and other compounds of the barbituric acid series, amiodopyrine, antipyrine, acetanilid, acetphenetidin, cinchophen. H 187 proposes that during the first thirty days after an injury to an employee an employer, coming within the terms of the workmen's compensation act, shall furnish the employee reasonable medical and hospital services. H 168 proposes to permit two or more neighboring towns to make appropriations for the joint support of the same physician, hospital, clinic or health center.

NEW JERSEY

Pharmacists Change Examination Dates—The Board of Pharmacy of the State of New Jersey announces that hereafter semi-annual examinations will be given in April and October for both the registered pharmacist and assistant pharmacist certificates in place of the examinations formerly conducted in January and July. The board will conduct examinations for registered pharmacists April 9 and October 15, and for assistant pharmacists, April 10 and October 16. Applications must be in the hands of the secretary at least thirty days before the date of the examination.

Health at Camden.—Telegraphic reports to the U S Department of Commerce from eighty-one cities with a total population of 36 million for the week ended January 31, indicate that the highest mortality rate (22.3) appeared for Camden and the rate for the group of cities as a whole was 15.2. The mortality rate for Camden for the corresponding period last year was 18.4, and for the group of cities, 13.7. The annual rate for eighty-one cities was 14.2 for the five weeks of 1931 as against a rate of 13.1 for the corresponding weeks of 1930. The rates published in this summary are based on mid-year population estimates derived from the 1930 census. Cities whose population was found to be less than was indicated by estimates heretofore used will therefore appear as having a higher death rate than usual even though there may have been no material increase in the actual number of deaths.

Bills Introduced—S 63 to amend the workmen's compensation act proposes to eliminate the statutory definition of hernia as ordinarily a disease and only rarely an accident and

as presumptively of either congenital or slow development in the absence of a tear or puncture of the abdominal wall. Proof of the industrial origin of a hernia may be by preponderance of evidence and need not as at present be conclusive proof. Time for the manifestation of symptoms after the event alleged to have caused the injury, within which industrial origin is to be presumed, is extended. Detailed provisions of the present law defining the relative responsibilities of employer and employee for the treatment of an industrial hernia will be eliminated if this bill be passed. A 105 proposes to permit any two or more associations or corporations maintaining a hospital, infirmary, dispensary or clinic in the same or adjoining counties, and supported in whole or in part by private charity, to merge or consolidate into a single corporation.

NEW YORK

The End of New York Health Demonstrations—Eight years after its inauguration, the New York health demonstrations project of the Milbank Memorial Fund terminated Dec 31, 1930. In both Cattaraugus County and Syracuse, local agencies have assumed the maintenance of the health activities growing out of the demonstrations, and the future cooperation of the fund in these localities will be confined to the support of research or other experimental projects growing out of the local demonstration experiences. The metropolitan demonstration will continue as an individual project. The board of supervisors of Cattaraugus County recently voted to increase the budget for the Cattaraugus County Board of Health. The decrease in deaths among infants is one notable result of the program and is indicated in a resolution as one of the reasons for the board's continued support of the activity.

Bills Introduced—S 385 proposes that a certificate of birth, in addition to the information now required, shall contain the mother's finger prints and foot prints of the child. A 143 proposes to prohibit experiments on living dogs. A 492, to amend the workmen's compensation act, proposes to allow injured employees to select their own physicians. A 573 makes it unlawful for any person to possess any apparatus designed for the use of opium. S 648 proposes to amend the law in relation to vaccination so as to provide that whenever smallpox exists in any school district the school authorities shall exclude from school for a period of fourteen days every child or person who does not furnish a certificate from a duly licensed physician of successful vaccination or show evidence by scar of a successful previous vaccination. If new cases of smallpox continue to develop after the expiration of fourteen days, the school authorities may renew such order for another period of fourteen days. No minor child shall be compulsorily vaccinated without the consent of its parent or guardian and no child shall be excluded from any public school in the absence of smallpox in the school district. A 574 proposes to make it unlawful to obtain habit-forming drugs from one physician while receiving treatment from another without disclosing that fact. A 584 to amend the workmen's compensation act, proposes to make all occupational diseases, arising out of an employment, compensable.

New York City

Personal—Dr Francis W. White has been appointed surgeon director to the throat department of the Manhattan Eye, Ear and Throat Hospital and Dr Edmund Prince Fowler, surgeon director to the ear department.—Dr Karl Landsteiner of the Rockefeller Institute for Medical Research was recently elected an honorary member of the Royal Swedish Academy of Science.—Dr Angenette Parry was recently decorated by the Greek government in recognition of service rendered sick and destitute refugees at the American Women's Hospitals, Kalamita, Piraeus, Greece.—Dr William W. Peter, New York, will go to China in February to help organize a health program for the Nationalist government. He is expected to spend about eight months in this work. Dr Peter was one of the founders of the China Council on Health Education of which he served as director from 1911 to 1926.

NORTH CAROLINA

Bill Introduced—S 117 to amend the laws relating to professional nursing proposes (1) that the examining board be designated the North Carolina Board of Nurse Examiners, (2) that all applicants have a high school education, (3) apparently that all persons who practice nursing come within the provisions of this act except the nursing of the sick by friends or members of the family.

NORTH DAKOTA

Bill Introduced—S 109 proposes to designate as illegal conduct, and as such sufficient cause for the revocation of a license to practice dentistry, certain forms of advertising of a character tending to deceive or mislead the public.

Society News—Dr Julius O. Arnson, Bismarck, and Attorney Fred T. Cuthbert, Devils Lake, addressed the Devils Lake District Medical Society January 28, on "Clinical Recognition of the Cardiac Irregularities with Remarks on Management of Congestive Heart Failure" and "Legal Medicine," respectively.

Twelve Deaths from Food Poisoning—Botulism poisoning from pea salad served at a party at the farm home of Edward Heim, Grafton, January 29, is believed to be the cause of twelve deaths reported up to February 2. Eight persons who also attended the gathering had shown no symptoms at the time of this report. The toxic material affected all the victims in practically the same manner and with one exception all were conscious until death and suffered no extreme pain. All complained of dizziness and impaired vision as the first symptoms, followed by failing sight and congested lungs. The midnight lunch consisted of "buns and wieners, olives, apples, two kinds of cake, and a pea salad, which included home canned peas, sliced cheese and some mayonnaise dressing placed on a lettuce leaf." Five of the eight members of the Heim family were among the victims. The three surviving children ate none of the salad, one of the other four survivors ate a small amount, apparently with no ill effect, and the other three ate generous portions but became sick a short time afterward and vomited.

OHIO

Bill Introduced—H 140 proposes to provide that the state reimburse hospitals for care and treatment of indigent hurt in automobile accidents.

State Health Officer Appointed—Governor White appointed Dr Harry G. Southard, Marysville, state health commissioner of Ohio, January 23, to succeed Dr Charles A. Neal. Dr Southard has been health commissioner of Union County and Marysville since 1924, it is reported.

Dr Heuer Goes to New York—Dr George J. Heuer, surgical director of the Cincinnati General Hospital and Holmes professor of surgery in the University of Cincinnati College of Medicine, has been appointed surgeon-in-chief of the New York Hospital and professor of surgery in Cornell University, effective July 1. He will undertake the organization of the surgical department in the new plant of the New York Hospital-Cornell Medical College Association.

Another Unit in Medical Center Opened—The Lakeside Hospital, one of the University Hospitals of Cleveland, Western Reserve University School of Medicine was recently opened. The eight story building is white brick corresponding with the Institute of Pathology of the university, and has a capacity of 378 beds. The Leonard P. Hanna House, a private pavilion, extending at right angles from one end of Lakeside Hospital, was opened at the same time. With the opening of this unit the building program of the University Hospitals, announced four years ago (THE JOURNAL March 26, 1927, p 1012), is practically complete. The nurses' dormitory was opened in October, 1930, and the central service building in December.

OREGON

Bills Introduced—S J Res 12 proposes to create a narcotic hospital commission to consider the establishment of a narcotic hospital. S 54 proposes to regulate the sale of veronal, barbitol, chloral hydrate, adalin, luminal and all acid diethyl barbituric preparations. S 53 proposes a new act to regulate the sale, possession or use of narcotic drugs and marijuana. S 163 proposes to abolish the state board of barber examiners and to vest all its powers and duties in a state barber examiner. H 202 proposes to accord liens to hospitals, physicians and nurses treating persons injured in accidents on settlements of judgments obtained by the injured persons by reason of such accidents. Such liens, however, shall not attach to settlements or recoveries had by reason of the workmen's compensation act.

PENNSYLVANIA

Bills Introduced—S 134 proposes to establish a state cancer institute and clinic. S 129 proposes to create a board of naturopathic examiners and to regulate the practice of naturopathy. All applicants for a license to practice naturopathy, however, prior to appearing before the naturopathic

board for examination would be required to pass an examination given by the state board of medical education and licensure, in anatomy, physiology, pathology, bacteriology, hygiene, biochemistry, symptomatology and diagnosis. H 331 proposes to regulate the practice of barbering. H 360 proposes that, in court hearings to determine the right of one committed to any mental hospital to a discharge therefrom, the court may in its discretion admit in evidence the sworn statement of hospital physicians.

SOUTH DAKOTA

Society News—At a meeting of the Aberdeen District Medical Society, Aberdeen, January 20, addresses were made by Drs. James B. Carey, Minneapolis, on Classification and Management of the Anemias; Edward P. Cathcart, Rochester, Minn., 'Value of Urography in General Diagnosis'; and Geoffrey I. W. Cottam, St. Paul, 'Intestinal Obstruction'.

Bills Introduced—S 64 and H 99 propose to provide for the collection, recording and preservation of vital statistics under the supervision of the state board of health. S 96 proposes to regulate the practice of chiropody, defined as the local medical, mechanical or minor surgical treatment of the human foot and massage in connection therewith excluding, however, the amputation of a toe or toes, the removal of any bone, or the use of anesthetics other than local.

TEXAS

Bills Introduced—S 78 proposes to define "poison" within the meaning of the pharmacy practice act to mean any drug, chemical or preparation which according to the United States Pharmacopeia National Formulary or materia medica is liable to be destructive to human life in quantities of sixty grains or less. H 334, to amend the nursing practice act, proposes that the board of nurse examiners consist of six members, two of whom serve for six years, two for four years and two for two years. H 251 proposes to levy an annual occupational tax of \$50 on itinerant physicians.

Annual Clinical Conference at Dallas—The third annual spring clinical conference of the Dallas Southern Clinical Society will be held, March 30-April 3 in Dallas with headquarters at the Baker Hotel. The lectures included in the graduate courses are grouped in fourteen divisions representing the major specialties in medicine. Beginning at 2 p. m. daily from Monday through Thursday, a group of organized clinics will be held in each of six Dallas hospitals. The annual clinic dinner and alumni gathering will be held Wednesday evening. A symposium on "Foreign Bodies of the Food and Air Passages" will be held Tuesday, and on Thursday one on hypertension. The round table luncheons will be held in four groups: surgery, pediatrics, medicine and eye, ear, nose and throat. A program of motion pictures, some with sound, has been prepared. Scientific exhibits will depict among other subjects, tularemia, undulant fever, Rocky Mountain spotted fever, psittacosis, endemic typhus fever and rabies. Technical exhibits are also planned. Drs. John R. Caulk, St. Louis, James H. Means, Boston, Willis C. Campbell, Memphis, Tenn., Conrad Berens, Jr., New York, and John Osborn Polak, Brooklyn, are included in the list of guests, some of whom were noted in THE JOURNAL, January 24, p. 279.

UTAH

Bill Introduced—H 56 proposes, in effect, to create a board of naturopathic examiners.

VERMONT

Bills Introduced—H 116 proposes to regulate the practice of naturopathy, which is defined as a system of treatment for the human body by the use of psychological, mechanical and material health sciences to aid in purifying, cleansing and normalizing human tissues for the preservation or restoration of health according to the fundamental principles of anatomy, physiology and applied psychology, as may be required without medicine or surgery. H 155 to amend the optometry practice act, proposes (1) to repeal that section forbidding the practice of optometry from door to door or from town to town; (2) to define gross unethical or unprofessional conduct which is sufficient cause for the revocation of a license to mean (1) advertising which has tendency to deceive the public; (2) practicing under an assumed name; (3) lending of certificate or license to any other person; (4) the employment of unlicensed persons in the performance of any services for which an optometrist's registration is required by law.

GENERAL

Reunion of Ex-Interns—Former interns of the Old Cincinnati Hospital will assemble from all parts of the country at the Cincinnati Club, Cincinnati, February 21. A large composite picture has been made of the present living interns of whom there are about 200, and will be presented to each attending the dinner. The secretary of the Ex-Interns' Society is Dr. Samuel Zielonka, Vendomissa Building, Cincinnati.

Nine Per Cent of Drugs Detained—According to Mr. W. R. Wharton, chief of the eastern district, Federal Food and Drugs Administration, U. S. Department of Agriculture, 9 per cent of the total drugs examined during the year ended July 31, 1930 were detained as violating the federal Food and Drugs Act. The district examined 2,763,620 pounds of cod liver oil of which 444,389 gallons was detained. More than 250 varieties of crude drugs offered for importation were covered in 3,593 shipments, which totaled 61 million pounds exclusive of cod liver oil. Mr. Wharton says that importers of crude drugs can assist in the correction of conditions leading to the necessity for detentions of illegal products at American ports by specifying only lawful merchandise. In order to bring about fundamental correction of abuses in the import trade in crude drugs, the administration seeks the support and cooperation of importers in enforcing the Food and Drugs Act. The following examples indicate the reason the drugs were detained: (1) recomite moldy; (2) roses, excessive moisture; (3) cinchona low alkaloids; (4) cod liver oil, adulterated with other fish oils high free fatty acids; (5) ergot, low potency and excessive foreign matter; and (6) ipecac, low alkaloids.

Medical Bills in Congress—Minority views, in opposition to the enactment of S 255, the Jones maternity and infancy and rural hygiene bill, have been filed by Representative Merritt, Connecticut, and Representative Beck, Pennsylvania. S 2817 has passed the Senate amending an act entitled "An Act to recognize the high public service rendered by Major Walter Reed and those associated with him in the discovery of the cause and means of transmission of yellow fever," by including Roger P. Ames among those honored by the act. S 5984 has passed the Senate, authorizing the construction, for the District of Columbia, of a sanatorium for adult tuberculous patients. H R 3394 has passed the Senate, providing for the deportation of aliens convicted and sentenced for violation of any law regulating traffic in narcotics. H R 6997 has passed the Senate providing free hospitalization for certain persons who served in the Quartermasters Corps or under the jurisdiction of the Quartermaster General during the war with Spain, the Philippine Insurrection or the China relief expedition. H R 12169 has passed the House proposing to define what constitutes the practice of naturopathy in the District of Columbia. H R 16162 has been reported to the House, without amendment proposing to extend hospital and home facilities to veterans of the Confederate army and navy (Report 2598). S Res 437 introduced by Senator Broussard, Louisiana, proposes to direct the Secretary of Commerce to furnish the Senate with copies of all cooperative or other agreements between the Bureau of Mines and any manufacturer of wood alcohol. S 5949 introduced by Senator Bingham, Connecticut, proposes to authorize the enlargement of the veterans' hospital in Connecticut. S 6090 introduced by Senator McKellar, Tennessee, and H R 17034 introduced by Representative Britten, Illinois, propose to regulate the interstate transportation of methanol. S 6097 introduced by Senator Wheeler, Montana, proposes to construct and equip a hospital on Crow Indian Reservation. S 6125 introduced by Senator Smoot, Utah, proposes to authorize an appropriation of \$20,877,000 to provide additional hospital and domiciliary facilities for veterans. H R 16915 introduced by Representative Leavitt, Montana, proposes to authorize the purchase by the federal government of the state laboratory at Hamilton, Mont., constructed for the prevention, eradication and cure of spotted fever. H R 16946, introduced by Representative Cable, Ohio, proposes the erection of a veterans hospital in northwestern Ohio. H R 16982 introduced by Representative Rogers, Massachusetts, proposes to authorize an appropriation of \$12,500,000 to provide additional hospital, domiciliary and outpatient dispensary facilities for veterans. This bill has been favorably reported. H R 17009 introduced by Representative Luce, Massachusetts, proposes to create a commission to study the hospitalization of veterans. H R 17031 introduced by Representative Fulmer, South Carolina, proposes to provide for federal cooperation with the several states in the care, treatment, education, vocational guidance and placement and physical rehabilitation of crippled children.

Pregnancy and Tuberculosis

At a joint meeting of the Tuberculosis Association and the obstetric section of the Royal Society of Medicine an important discussion took place on the subject of pregnancy and tuberculosis. Dr Geoffrey Marshall, tuberculosis officer of Guy's Hospital, said that academically every woman in this country could be said to be tuberculous, as every adult harbored bacilli, more or less. But a tuberculous woman meant one whose health had been seriously impaired by disease of the lungs. Should pregnancy be allowed to continue? Older writers, from Hippocrates to Sydenham regarded the pregnancy as beneficial to the lung disease, but more recent ones, including Osler, held that the pregnancy was a disaster. The pendulum was now swinging to a neutral position, but most physicians dreaded pregnancy in a tuberculous woman. If it had passed the fourth month artificial termination was rarely advisable, many would not sanction it later than the end of the second month. But in several cases it had been stopped in the fourth month without increasing the pulmonary trouble. In early pregnancy the guide was not so much the extent of the disease as its history. When the disease had only recently become active or had recently become quiescent, nonintervention would be difficult to justify. When the disease was chronic, pregnancy was seldom disastrous. Moreover, a patient in whom the disease had been arrested stood an anesthetic and the operation well but pregnancy badly. On the other hand, in the advanced or chronic case anesthetics were not so well borne, nor were operations, while pregnancy did less harm.

In the medical management, the important point was that pregnancy was an additional reason for inducing pneumothorax, if the case was suitable, i. e. the disease confined to one lung. In the puerperium the question of nursing arose. There was no hard and-fast rule. If pregnancy and parturition had been gone through without disturbance, no sudden change was likely to occur in the puerperium. If weight was not falling and there was no pyrexia nursing might in most cases be allowed.

The obstetrician's standpoint was put by Mr Aleck Bourne of St Mary's Hospital. He first referred to the conflict of opinion as to the effect of pregnancy on tuberculosis and the treatment. This he attributed to the fact that no one observer had sufficient experience of both aspects of the question and therefore views were based on inadequate material. His own view, formed after twelve years work in an infirmary was that tuberculous women should be informed that pregnancy was of no consequence when the lesion was healed and inactive but unfortunate when the disease was active and disastrous when advanced. Abortion in general had no place in the treatment. In the puerperium the essential thing was to disallow lactation and if possible to remove the child from the danger of infection. For phthisis as for other diseases the proper course was to treat the disease and leave the pregnancy alone.

Another obstetrician Mr L. C. Rivett of Queen Charlotte's Hospital said that in active tuberculosis abortion should be induced for the sake of both mother and child. Any woman who had active tuberculosis should receive sanatorium treatment during the whole of her pregnancy and for six months afterward. The tuberculosis had little effect on the pregnancy; there was no particular tendency to abortion. The child was usually on the small side and there was no reason to interfere with the labor especially as anesthetics were inadvisable. There was no tendency to postpartum hemorrhage, sepsis or subinvolution. He advocated no nursing.

In the discussion, the same differences of opinion between the physicians and the obstetricians were revealed. Thus, Dr Jane Walker was surprised at the opposition to nursing. Her own view was that it was an advantage to both mother and child that nursing be allowed. On the other hand, there was general agreement as to the artificial termination of pregnancy only in the early stages and as to the value of the pneumothorax treatment. The hope was expressed that the ministry of health would, as the result of the discussion make provision for the treatment of pregnant tuberculous women. But Dr Jane Walker pointed out that after consulting with Dame Louise McIlroy, professor of obstetrics at the London School of Medicine for Women, and herself, the London county council had under consideration a scheme for tuberculous women to be sent to a sanatorium for confinement and the ensuing six months. But it was found that the women objected to going.

Influenza in England

Influenza is prevalent in England, as it often is at this time of the year and as it is at present in other parts of the world, but its virulence is low. For the week ended January 17 there were registered in the 107 county boroughs and large cities 146 deaths from influenza, of which 27 were in London. For the previous week the numbers were 101 and 16. An influenza wave usually lasts about six weeks. The disease has reached epidemic prevalence at Aldershot where a large number of troops are always stationed, but the majority of the cases are mild. The usual precautions for an epidemic have been taken. Soldiers have been advised to avoid crowded places and to gargle night and morning with a mixture of potassium permanganate and sodium chloride. Meetings at the military welfare centers for women and children have been canceled.

Is Cancer Stimulated by Radium?

The Medical Research Council has just issued a report summarizing the records received from the research centers in London, Birmingham, Cardiff, Aberdeen and Dublin, which have been entrusted with stocks of radium salt by the government in order to investigate its curative powers. In the years during which roentgen rays and radium have been used as therapeutic agents two questions have from time to time been asked and have evoked discordant replies. One is: Do some people exhibit idiosyncrasies to irradiation? The other is: Do the rays occasionally stimulate malignant growths to increased activity? On the first question the report states that every now and then a patient of unusual sensitiveness does appear. On the second question opinions differ widely. There are several possible modes of stimulation of malignant cells. On the general principle, established for so many drugs that large doses and small doses may act in opposite ways it might be thought that living cells can be stimulated by very small doses of irradiation. In the vegetable world both positive and negative results have been reported and some observations suggest that this may hold for malignant cells but they are too few for definite proof. Another way in which radiation may possibly stimulate malignant growths is by giving a considerable dose to a growth already infected with bacteria. Here a total different series of events must be visualized for the reaction of a malignant growth to irradiation is partly caused by the direct action on the cells themselves and partly by indirect action on the normal tissues of the host. In the case of infected growths it is perhaps rational not to expect the normal series of reactions and in extreme cases it is possible that malignant growths do increase at a more rapid rate than they otherwise would in spite of the damage the malignant cells themselves may have suffered from the direct radiation. The report draws attention to a case at the Middlesex Hospital in which progress of the disease seemed to be accelerated by the treatment. Whether this resulted from the opening up of fresh channels by the needles that were inserted or from the action of the

rays on the cells or surrounding tissue cannot be said. Which of these alternatives is correct is clearly a question of fundamental importance in radium therapy.

Definite lines of treatment by radium for different parts of the body have now been approved as effective. Particularly good results have been obtained from the Paris and Stockholm methods, which differ only in small details. Great Britain has been late in obtaining such adequate supplies of radium as have been available on the continent for several years. But it has already won respect by its contributions to radium therapy, and it may yet be that a 'British method' for some of the more resistant regions of the body may receive approval. It is already clear that some persons are especially sensitive to radium and that their sensitiveness has to be carefully estimated before conducting the treatment. In some cases, again, the rays seem to stimulate rather than to destroy the malignant growth.

The Control of Opium Smoking in the Far East

The report of the commission of inquiry into the control of opium smoking in the Far East came before the council of the League of Nations at Geneva. The conclusions of the commission were that all measures aiming at gradual suppression should be taken concurrently in each country, that it was necessary to secure the gradual limitation of poppy cultivation, that the price of government opium should be reduced so as to make smuggling unprofitable, that government opium should be distributed through only state controlled shops, that smoking should be prohibited to any one under the age of 21 years, that the consumption of drugs being more harmful than that of opium, its strict control must also be established, and that governments that derive revenue from the sale of opium must readjust their budgets. It was decided to accept the invitation of the Siamese government to hold a conference on opium smoking in Bangkok in November.

The Relation of Physicians to the Clergy

The question of faith healing and the relations of the clergy with physicians in the treatment of the sick have become prominent subjects in the discussions of the Church of England, partly as the result of the considerable support given to so-called Christian science, which has been introduced into this country from America. At the convocation of Canterbury, just concluded, there was a discussion regarding the ministry to the sick, with especial reference to the use of unction and the laying on of hands. Rev. T. F. Mountrun said that much so-called faith healing was due to natural causes, and the faith that was necessary was subjective rather than objective. That was why they saw so many cures from so-called Christian science. It should be emphasized that what they were doing in unction was something for the soul, and a secondary consequence might be the healing of the body. The Bishop of Woolwich said that for the first time in history all the bishops of the Anglican communion had approved of the principle of spiritual healing and it seemed fitting that a special form be adopted for use. Physicians were realizing more and more the necessity of spiritual agency in their work. They had no antagonism to the clergy but were perfectly willing to cooperate and it was that cooperation the church wanted to bring about. The church had neglected spiritual healing too long and in consequence there had been a growth of Christian science.

Presentation to Sir D'Arcy Power

Sir D'Arcy Power, who has just returned from lecturing in America, has been presented with a volume of selected writings from his own work in commemoration of his seventy-fifth birthday. The presentation was made at Sir D'Arcy's hospital, St. Bartholomew's, by Lord Moynihan, who described him as the most eminent medical historian of our day. The *British Journal of Surgery* had greatly benefited by his unrivalled knowledge of

surgical history. Of the sixteen articles in the commemorative volume, all but two are on historical or biographic subjects. The two surgical articles are on the palliative treatment of mercury and on cancer of the tongue. Sir D'Arcy makes the important point that there is no record of the latter disease before 1635 and that its increase has been parallel with the increased use of tobacco.

PARIS

Hypotensive Properties of Sodium Oleate

In an address delivered before the Société des médecins des hôpitaux de Paris, Dr. Maurice Renaud called attention to the unexpected effect of a marked reduction in blood pressure following the intravenous injection of a solution of sodium oleate. The mechanism of its action appears to be quite different from that of substances that act on the vasomotor system. From researches made thus far, it is evident that the intravenous injection of sodium oleate does not cause disorders in the organism that need be feared. It acts on the arterial pressure, causing a steady and permanent reduction after the lapse of several hours which amounts to from 6 to 10 degrees on the Pichon sphygmomanometer; the minimum pressure declining almost parallel with the maximum pressure while the oscillographic relation increases. The action appears to be more effective, the higher the pressure is. In persons with high blood pressure, injections of sodium oleate cause regularly a marked lowering of the arterial hypertension and appear to be by far the most effective means for diminishing the dangers. Finally, while the physiologic mechanism remains to be studied, what is known of the properties of soaps leads to the belief that the injection of sodium oleate causes only purely physical modifications in the conditions of the circulation. The study of the problem ought to elucidate the pathogenesis of hypertension.

The Sanitary Control of Aviation

Discussions on the sanitary control of aerial navigation resulted in the promulgation of several resolutions by the permanent committee of the International Bureau of Public Hygiene, at its recent meeting in Paris. Several countries have regulations on this subject, some of which are rigorous. The committee expressed the view that it would be well to present a typical set of regulations that might serve as a model for all countries, in order that uniformity might characterize their administration. A subcommittee was appointed and authorized to appeal for aid to the Commission internationale de la navigation aérienne. The subcommittee concluded that, under present conditions, which are subject to change from day to day, it would be premature to try to establish a set of regulations or even general principles, and that the regulations adopted, such as they are, will necessarily, at the start, be subject to more or less complete revisions. The committee emphasized again the danger of patterning regulations of sanitary defense, as affecting aerial traffic after the regulations governing maritime navigation. The point was stressed that the risk of dissemination of disease by airships is relatively slight by reason of the class of passengers and the conditions existing in the landing ports. It decided therefore, that the International Bureau of Public Hygiene, in advising the governments and the organizations interested of the conclusions reached with reference to the question of international sanitary regulation of aerial navigation, should call their attention to the principles adopted by the committee at its session last May, that is to say: (a) established landing fields, (b) medical examination on arrival, (c) sanitary surveillance of persons coming from infected regions, (d) in special and exceptional cases rendering such measures necessary, strict isolation during the port calls. To these it would be well to add two others:

1 The buildings, the occupants, and, in general, the whole area of the airports, should be maintained in an absolutely sanitary condition, and the precautions, in the yellow fever regions, should include mosquito proofing and measures for the destruction of mosquitoes. 2 Wherever the need is felt, special arrangements should be made for the creation of a system of communication between the physicians of the airports located on the same route, concerning infectious diseases. It should be emphasized that these recommendations do not include the institution of a system of clearance papers such as is employed in maritime navigation nor do they provide for the 'observation' of passengers. In this connection, in recent research, Pettit, Stefanopoulou and Roubaud showed that the Algerian monkey is highly susceptible to yellow fever. They ascertained that the species of *Stegomyia* in regions exempt from yellow fever are just as capable of transmitting the virus as are the species of *Stegomyia* found in endemic regions. Particularly, the species of *Stegomyia* found in northern Africa is capable of being the vector of the virus. These facts are important for hygienists to know at this time when airships may transport a yellow fever patient who is still infectious to a country is yet exempt.

International Exchange of Professors

At the request of Mr Briand, the minister of foreign affairs who desires to promote the international exchange of university professors, the minister of public instruction requested the council of the Faculté de Paris to designate an eminent professor who would be invited to deliver a number of lectures at the University of Paris. Accordingly at the request of the Faculté de Paris Professor Jadassohn of Germany came to Paris and delivered three lectures on dermatosyphilography. The topics were (1) hematogenic toxidermias (2) relations between the allergy, the histologic structure of dermatoses and the number of micro organisms and (3) discussion of anti-syphilitic treatment. Professor Jadassohn discussed from his wide experience, the present state of knowledge of these three great questions pointing out what had been acquired and what was still hypothetical, what remained unknown, and what lines of research should be pursued. The lectures were delivered before practically all the dermatologists of Paris and many other physicians and students, both French and foreign.

Report of the Sanitary Inspection Service of Paris

Mr Roeland member of the municipal council of Paris, has recently published his report on the veterinary sanitary inspection service of the city of Paris and of the department of the Seine. It will be noted that rabies has almost entirely disappeared although the number of dogs has increased. From 166,917 dogs in Paris in 1924 the number had risen in 1929 to 230,674. In spite of this marked increase only ten cases of rabies in animals were observed. There were no cases of rabies in man. The report of Mr Roeland brought out the fact that the consumption of meat has diminished likewise less poultry and game were consumed. On the other hand the Parisians seem to be eating more fish mollusks and crustacea. Paris received 179,661,009 eggs. All these food products were subjected to strict sanitary control the details of which Mr Roeland describes. The report gives a detailed account of the sanitary control of milk to which great importance is attached in spite of the opinion of a government official to the contrary. The control of milk is effected through the vigilant supervision by the services of the prefecture of police, which gives this matter particular attention.

Tuberculosis in the French Colonies

From an inquiry published by Dr Abitucci it appears that the diffusion of tuberculosis in the French colonies follows the same laws as in Europe. It is rare in regions where the natives live in scattered dwellings with rare contacts with

white persons. But following such contact, the disease, evolving in a virgin soil, develops rapidly. In Africa that fact is evident. Tuberculosis is common on the coast and diminishes rapidly in frequency as one penetrates to the interior. When the black troops were brought to France, during the war, the Senegal contingents, as a result of careful examinations on their arrival in the camps at Frejus and at Saint Raphaël, were found to present only from 4 to 5 per cent of positive skin reaction. Tuberculous morbidity in them increased rapidly as the war progressed and at the close of 1919 amounted to 23 per thousand. It was only 4 per thousand in 1923 and 1924, on their return to Africa. Tuberculosis is widely prevalent in the Indies, on Reunion Island in Guiana, and especially in the colony of Saint Pierre and Miquelon, where its development is favored by the spread of alcoholism. In New Caledonia a French penal colony, former convicts who have become colonists have spread the disease among the natives, who were previously immune. In Madagascar, tuberculosis is frequent among the Hovas of the high plateau regions but more rare among the inhabitants along the coast. In the Antilles, the blacks, during slavery times, living *en famille* with the planters were well fed and well taken care of and seldom developed tuberculosis. Having gained their liberty, they lived in promiscuity in unhygienic dwellings, so that the skin reaction to tuberculin is now around 40 per cent. In Indo China, tuberculosis is rare in Laos which is isolated owing to its mountain and forest frontiers but it is increasing in all other parts of the colony, which is due to the constant mingling of the races in the exchange of commodities. Its frequency is as in Europe in direct relation to the density of the population. In Cochinchina, with a dense population, the proportion of positive skin reactions reaches 67 per cent as in Europe. It is in this province that the government has undertaken an antituberculosis crusade on the same basis as in France with the aid of the services of the Pasteur Institute at Saigon. The organization comprises dispensaries open in schools for suspected children, sanatoriums and, in the hospitals, special wards for the treatment of advanced cases. At the same time a publicity campaign is carried on in the native language by means of leaflets and articles in the press, which the teachers are requested to call attention to in the public schools and by the aid of lectures and the projection of films. Vaccination with the BCG vaccine is applied to the new born in Indo China and in French West Africa to adults with a negative skin reaction in Madagascar and in French West Africa and to men beginning their military service in France and in the colonies. The laboratories of Saigon, Tananarive and Dakar receive from the Pasteur Institute in Paris the required strains of organisms with which to prepare the vaccine on the ground under the best possible conditions.

The Third Normal Heart Sound

Dr J. Barbosa Corrêa assistant physician to the Clinic of the Faculty of Medicine of São Paulo recently lectured on the diagnosis of cardiac murmurs. He described the characteristics of the third heart sound which although described in 1907 by means of graphs by Enthoven and clinically by Gibson is still unknown to some clinicians. The speaker was able to discover the third cardiac sound while auscultating the hearts of normal students aged from 18 to 21 years. The phenomenon which appears at the beginning of diastole is characterized by a brief weak sound with greatest intensity at the moment of its cessation. The strokes of the third heart sound may be represented thus: TLM-ta-tum TLM-TA-tum. In some cases the intensity of the sound increases during the examination the patient is placed in lateral decubitus on the left side, after having taken moderate exercise. In some cases the sound is so characteristic

that this procedure is unnecessary. The site of the greatest intensity of the sound is the apex. Owing to the fact that the sound is weak, it cannot be heard in other cardiac areas. The mechanism by which the third heart sound is produced has been explained by some authors as being due to the sudden distention of the ventricular wall caused by the first flow of blood while the latter enters the ventricle at the beginning of diastole. According to other authors the third sound is caused by vibrations of the auriculoventricular valves when they are opened by the force of the blood while the latter goes into the ventricles. The differentiation of the normal sound from the pathologic murmurs that arise during the prediastolic stage is important, since both the normal prediastolic sound and some accidental murmurs that are characteristic of mitral stenosis are heard at the apex. That is why some cardiologists have admitted the possibility that a diastolic murmur may simulate the second heart sound. Sometimes the diastolic murmur is short and the diagnosis of its presence is rather difficult when no other symptoms of aortic insufficiency are present. In doubtful cases of this nature, in order to make a differentiation of the sound as being either normal or pathologic the following considerations should be kept in mind. According to Lewis's observations, the presence of a prediastolic murmur independent of a presystolic murmur in patients with mitral stenosis points out that there exists a delay in the conduction. Josue has demonstrated that, in the auscultation at the jugular vein, a weak sound preceding the first heart sound is heard at the moment of the contraction of the auricle, which sound gives the impression of a presystolic cantering rhythm, whereas, if there is a delay in the conduction, the sound that corresponds to the systole will arise just after the second heart sound. In auscultation over the jugular vein, the prediastolic murmur caused by mitral stenosis is heard in association with a rhythm similar to the prediastolic gallop, while the normal prediastolic sound, that is, the third heart sound is heard in association with a rhythm which is similar to the presystolic gallop. Once the third heart sound is known it cannot be mistaken for pathologic bruits, which have a different site of greatest intensity and which give a different acoustic impression. There are, however, some bruits, such as is the case with the prediastolic murmur, which give the same acoustic impression that the normal heart sound gives. The differentiation is made because the third normal heart sound is observed in healthy young people without symptoms of cardiac diseases. When the differentiation between the conditions mentioned is difficult, electrocardiography, and sometimes sphygmomanometry, is of value in solving the diagnostic problem.

Tracheobronchial and Tracheo-Esophageal Fistulas

Dr. Mangabeira Albernarz recently published an article on the relations between the respiratory passages and the digestive tract. He points out the most frequent localizations of tracheobronchial and tracheo-esophageal fistulas and the etiologic factors that are involved in the development of the fistulas. Cancer is the most common origin, coming next in importance to congenital fistulas, of which the author has found 222 in his review of the literature. Syphilis is rarely the origin of this type of fistula. Out of 639 cases reviewed in the literature only 20 cases were syphilitic. Etiologic factors of less importance in the formation of this type of fistulas are tuberculosis, actinomycosis, internal or external trauma and decubitus of the patient or some other similar cause. One patient developed a fistula after having been wounded by a gun. The bullet went in 1 cm. to the right of the median line and 2 cm. above the clavicular articulation and it was lodged at the opposite side in the interior border of the trapezium. Great care was taken to avoid the development of a deglutition pneumonia and also of mediastinitis as possible complications of the wound. A prophylactic mediastinotomy according to Maschik's method was made. Notwithstanding these precautions the patient died in a violent

hemorrhage due to the rupture of the left vertebral artery which was injured by a fragment of the seventh cervical vertebra. The fracture of the vertebra had not been discovered. The author considers this case rare.

Trachoma

Drs. Fabio Belfort and Flury de Silveira recently delivered lectures before the Sociedade de Medicina e Cirurgia de São Paulo on their studies of trachoma. The speakers concluded that trachoma is a contagious disease. The bacteria of trachoma are not detectable by the methods available for the visualization of bacteria. The statement previously made that trachoma is a condition of chronic conjunctivitis which results after one or several attacks of acute conjunctivitis, either insufficiently treated or not treated at all during the acute inflammatory stage is incorrect. Acute conjunctivitis of a chronic type is caused by *Hemophilus* of Koch-Weeks and by *Hemophilus* of Morax-Axenfeld. Trachoma may be treated by the nasal route. Trachoma may have a subacute beginning, it is not associated with ocular suppuration and it is not in all cases a chronic disease. Adults are not immune to trachoma and there is not less resistance to the disease in adults than in children. Care of oneself and the observance of hygienic precepts prevent contagion. The patient studied by the authors was 55 years old.

Germany's Physicians

According to the 1931 edition of the Reichs Medizinischer Kalender für Deutschland, Part II, Medical Handbook and List of Physicians comprising statements in regard to all physicians of the German Reich, a list of all hospitals and sanatoriums, a survey of the medical organizations of Germany, and similar material, there were about 50,000 physicians in the Reich exclusive of the Saar region as of October, 1930 and in addition 396 physicians in the Saar region and in the Free City of Danzig. In recent years, the number of physicians has increased much more slowly than during the first years following the inflation period. Women physicians have increased more rapidly than the total number of physicians. Whereas in 1909 there were only 82 women physicians, or 0.27 per cent of the total number of physicians, in 1930 there were 2,807 women physicians, or 5.95 per cent of the total number. The contingent of women among the new graduates has increased so rapidly that for each ten men physicians there are more than two women physicians. The marked decrease in the number of newly licensed physicians explains the noticeable lack of assistants. Over against the small number of newly licensed physicians stood a total of about 1,800 deceased physicians in the years 1929 and 1930, so that the past two years has not added materially to the excess of physicians and the apparent increase in the number of physicians in these two years is doubtless due to the fact that recent statistics are more accurate. This development, however, does not promise any lessening of the high percentage of physicians for the number of students who have passed the preliminary tests and the number of medical students do not indicate any decrease in the number of physicians for the immediate future. The increase in the number of medical students will soon effect an increase in the number of newly licensed physicians. On the other hand when the youths born during the war years enter the medical schools—especially if the present economic stress continues—there will doubtless be a reduction in the number of medical students. Furthermore the gradually increasing medical tasks that will result from the proportionate increase in the representation of the higher age groups in a few decades furnish increased employment for the medical profession, so that the economic crisis among the medical profession due to the excess

of physicians will then presumably yield to better economic conditions. In the meantime, until it becomes more evident just how things will be going, an endeavor must be made to prevent a too rapid growth of the medical profession, in order that the present crisis may not rest too heavily on the profession.

Of the 49,974 physicians in the German *reich* there were 2,794 physicians who were directors of institutions and 7,041 physicians who occupied other posts in institutions, exclusive of the physicians serving in roentgen institutes, laboratories, pathologic institutes or polyclinics. In addition to the aforementioned institutional physicians, there were 37,246 free practitioners and 2,893 physicians who have retired from active practice.

Of the total number exclusive of the 2,893 nonpracticing physicians, which constitute 5.8 per cent of the total 32,629 are general practitioners, which includes the specialists in physiotherapeutic therapy, roentgen diagnosis and therapy, medicomechanics and diseases of the mouth and the jaws, and 14,452, or 28.9 of the total, include the other specialties. Of this number, 24.4 per cent are internists, 16.7 per cent are surgeons, 11 per cent are gynecologists, 8.2 per cent are pediatricians, 6.4 per cent are psychiatrists or neurologists, 9.1 per cent are oculists or ophthalmologists, 10.2 per cent are laryngologists, rhinologists and otologists, and 1.4 per cent are dermatologists and urologists.

The percentage of physicians in a given area is naturally greatly affected by the large cities and the universities. There is an especially high percentage of women physicians in the large cities.

Eruptions Induced by the New Style of Hats

Prof W. Frei, writing in the *Deutsche medizinische Wochenschrift*, calls attention to skin eruptions on the head, induced by the present style of hat worn by women. He has observed four such cases recently, so that he is convinced that the eruption must be of common occurrence. The disorder has nothing to do with hair tonics and hair dyes, which are the more frequent cause of eruptions on the head. It may, however, have some analogy to the eczemas observed, a few years ago, on the heads of men, which were caused by hat sweat bands made of artificial leather, employed to some extent during the inflation period for the headdress of women is apparently the inducing cause. The four women who presented the irritative and stubborn eruptions had all worn the tight-fitting hats that are now so much in vogue, and the eczemas corresponded precisely to the areas of the scalp against which the hats rubbed. While the localization of the eruptions pointed plainly to the hats as the inciting cause, this assumption was proved by means of irritation tests that Professor Frei carried out with the black lining and the black felt of the hats on the backs of the wearers. Other women, to be sure did not react to these irritation tests, hence it is evident that the disorder is based on a peculiar hypersensitiveness of the women affected. This hypersensitiveness is not directed against the fiber material of the hats but against the chemical substances contained in such material. That black dyes are concerned is possibly due to the fact that the dark color tones are dominant in the present style of hats. Likewise, it is doubtless due to the present style that the disorder is at present so common for the tight fitting hats such as are now worn bring the dangerous substances in so much closer contact with the scalp than was formerly the case. As the eruptions are persistent and highly irritative it is to be hoped that a change in the style will soon put an end to the eczemas.

Institute for the History of Medicine

Prof. Dr. Paul Dürpen, the medical historian, who was called from Freiburg to Berlin about a year ago, spoke recently before the Berliner Gesellschaft für Geschichte der Naturwissenschaften, Medizin und Technik on the aims and tasks of

the new institute for the history of medicine and the natural sciences, the erection, equipment and direction of which he took over on assuming his present post.

The institute has a suite of twenty-five rooms in a former bank building. The chief equipment consists naturally of the library treasures, which are, in part, so valuable that they are preserved in a special depository left by the bank. At present, the library comprises 10,000 volumes. In addition, there is a special pharmaceutical collection of 2,000 pieces. A larger seminar room, which is well adapted for lectures, serves for the present as a reading room for the students. Then there are work rooms for the director, four assistants and other auxiliary personnel. The reading room, as well as the whole institute, will be open until a late hour. It is planned to organize the service so that the institute, by means of its comprehensive card filing system, will furnish information at any time on the existing literature in this particular specialty, in other words, a scientific source of information on a large scale. The principal task of the institute will be to instruct the students as to the importance of the problems of the history of medicine for the understanding of the medicine of the present day and to guide them in the making of independent researches in old documents, which has already led to historically important discoveries. At present, the institute is engaged in collecting material for the publication of an atlas of the history of medicine and of studies on Arabian medicine, in which latter task the orientologists of the university will cooperate.

Death of Professor Siemerling

Geheimer Medizinalrat Prof. Dr. Ernst Siemerling, one of the best known neurologists and psychiatrists, died, after a long period of suffering in the Charité Hospital, January 6, aged 73. This was the hospital in which he served many years previously as assistant under the nerve specialist Westphal. In 1893, after he had been appointed, a year previously, professor extraordinarius, he received a call to the University of Tübingen as ordinarius for psychiatry, and in 1900 he accepted an invitation to the University of Kiel, in the same capacity.

His scientific importance was far above the average. Importance attaches to his research on the delicate structure of the brain and the spinal cord; to his contributions to medicolegal psychiatry, to mental disease and crime and to the etiology of multiple sclerosis. His investigations on the incidence or softening of the brain among the female population of Berlin attracted considerable attention. After his retirement Geheimerat Siemerling led a quiet life in Berlin.

Marriages

GEORGE BRITAIN WALTON, Durham, N. C. to Miss Izzi Witherspoon of Greensboro, in Winston-Salem Dec. 12, 1930.

ROBERT C. ANDERSON, Johnson City, Tenn. to Miss Irene Hendrix of Petersburg, Va. in Bristol, Tenn. Nov. 8, 1930.

LILLIS COLUMBUS MOORE, Carthage, Miss. to Miss Catherine Preston Finney of Lexington, Va. in December, 1930.

JOHN W. GOOD, Cedar-town, Ga. to Miss Lois Bedwell of Cedar Bluff, Ala. in Center Ala. Dec. 5, 1930.

PIERRE WILSON MEADOR to Miss Ethel Marchant Hyde, both of Richmond, Va. in December, 1930.

JOHN JAMES BURR, Lake Linden, Mich. to Miss Marie Rahol of Iron Mountain, Nov. 11, 1930.

CLAYD WELSH, Aberdeen, Wash. to Miss Hazel Lehnert of Bismarck, N. D. in Seattle, recently.

VIVIAN P. SILGER, Collinsville, Ill. to Miss Jessie Little of Edwardsville, Nov. 27, 1930.

THOMAS W. KOON, Cumberland, Md. to Miss Fannie Hutson of Rawlins, Nov. 12, 1930.

THOMAS D. KECKICH, Gary, Ind. to Miss Helen Murat of Chicago, Nov. 27, 1930.

Deaths

Horace Bailey Pritchard, Syracuse N. Y., Syracuse University College of Medicine, 1904 member of the Medical Society of the State of New York and the American College of Surgeons, past president of the Onondaga County Medical Society, assistant professor of clinical surgery at his alma mater, served during the World War on the staff of the Hospital of the Good Shepherd, aged 51, died January 10, in Fort Lauderdale, Fla., of cerebral hemorrhage.

William Carlton Smith, Salem, Ore., University Medical College of Kansas City, 1898, past president and secretary of the Marion County Medical Society, at one time professor of anatomy, Willamette University Medical Department, served during the World War member of the state legislature, formerly on the staff of the Salem Hospital, aged 56, died, Dec. 24, 1930, in Portland.

Thomas Francis Reilly, New York, Bellevue Hospital Medical College, New York, 1896, member of the American College of Physicians, formerly professor of medicine, Fordham University School of Medicine, on the staffs of St. Vincent's Hospital, St. Elizabeth's Hospital and the Fordham Hospital, aged 59, died, January 24, of cerebral hemorrhage and arteriosclerosis.

Albert Buist Leeds, Poland, N. Y., University and Bellevue Hospital Medical College, New York, 1907, member of the Medical Society of the State of New York, health officer of the town of Russia and the villages of Coldbrook and Poland, served during the World War, aged 44, died Dec. 27, 1930, in the Faxon Hospital, Utica, of acute hemorrhagic pancreatitis.

Grant C. Markle, Winchester, Ind., University of Louisville (Ky.) School of Medicine, 1892, health officer of Winchester, formerly county coroner, and secretary of the city and county board of health, on the staff of the Randolph County Hospital, aged 62, died January 16, of injuries received when the automobile in which he was driving was struck by a train.

William Horton Pierson, Brooklyn, New York, Homeopathic Medical College, 1883, member of the American College of Surgeons, on the staffs of the Cumberland Street Hospital and the Prospect Heights Hospital, aged 73, died, January 29, in the Carson C. Peck Memorial Hospital, of chronic myocarditis, coronary sclerosis and chronic vascular nephritis.

William Duffield Robinson, Philadelphia, University of Pennsylvania School of Medicine, Philadelphia, 1880, past president of the Philadelphia County Medical Society, member of the American College of Physicians and the American Climatological and Clinical Association, aged 74, died, January 24, in the Lankenau Hospital, of pneumonia.

Burtis T. Green, Brookings, S. D., Hahnemann Medical College and Hospital, Chicago, 1903, president of the Madison County Medical Society, member of the American College of Surgeons, on the staff of the Wesley Hospital, aged 64, died, January 18, in the Midway Hospital, St. Paul, of ileus, following an operation for cholelithiasis.

Francis R. Sherwood, Oak Park, Ill., Rush Medical College, Chicago, 1888, at one time professor of surgery at the University of Illinois College of Medicine, formerly on the staff of the Cook County Hospital, aged 68, died, February 7, of arteriosclerosis and carcinoma of the rectum.

Arthur Abraham Husser, Havre, Mont., Bennett Medical College, Chicago, 1908, member of the Medical Association of Montana, served during the World War on the staffs of the Kennedy Deaconess Hospital and the Sacred Heart Hospital, aged 45, died, January 12, of pneumonia.

Hugh Thomas Nelson, Jr., Charlottesville, Va., University of Virginia Department of Medicine, Charlottesville, 1899, served during the World War, aged 54, died, January 15, in a sanatorium at Richmond, of hemorrhage of the femoral artery, which was pierced by a piece of glass.

John Merceur Green, Charleston, S. C., Medical College of the State of South Carolina, Charleston, 1891, member of the South Carolina Medical Association, formerly city health officer, aged 61, died, January 14, of arteriosclerosis and angina pectoris.

William Jay Donaldson, Commerce, Mich., Bennett College of Eclectic Medicine and Surgery, Chicago, 1898, formerly health officer of Commerce, aged 69, died, January 22, in the City Hospital, Pontiac, of injuries received when struck by an automobile.

Charles Hill Brooke, Baltimore, University of Maryland School of Medicine, Baltimore, 1891, coroner of Southwestern district of Baltimore city, aged 64, died, Jan. 28, in the Maryland General Hospital, of influenza and intestinal hemorrhage.

William M. Cole, Longview, Texas, Kentucky School of Medicine, Louisville, 1891, past president of the Gregg County Medical Society, for six years mayor of Longview, city county health officer, aged 66, died, January 5, of cerebral hemorrhage.

Oren Howard Cobb, Syracuse, N. Y., Johns Hopkins University School of Medicine, Baltimore, 1906, member of the American Psychiatric Association, superintendent of the Syracuse State School, aged 50, died, January 23, of heart disease.

James Hennessy, Emmetsburg, Iowa, Keokuk Medical College, College of Physicians and Surgeons, 1905, member of the Iowa State Medical Society, for many years county coroner, aged 55, died, January 15, in a local hospital, of pneumonia.

Erastus Thomas Barker, Oklahoma City, Okla., Memphis (Tenn.) Hospital Medical College, 1899, served during the World War, aged 60, died, Oct. 16, 1930, in the U. S. Veterans Hospital, North Little Rock, of cerebral hemorrhage.

David Wise, Carthage, Mo., St. Louis College of Physicians and Surgeons, 1892, Beaumont Hospital Medical College, St. Louis, 1893, member of the Missouri State Medical Association, aged 60, died, Dec. 9, 1930, of myocarditis.

Charles Allen Lamson, New London, N. H., Dartmouth Medical School, Hanover, 1891, member of the New Hampshire Medical Society, served during the World War, aged 65, died, Dec. 29, 1930, of cerebral hemorrhage.

Christopher Freeman Chaffe, Rochester, N. Y., Medical Department of the Tulane University of Louisiana, New Orleans, 1906, for twenty years county bacteriologist, aged 49, died, February 2, of gastric ulcer.

Jacob Lazar Hausman, Marysville, Kan., Ensworth Medical College, St. Joseph, 1895, member of the Kansas Medical Society, formerly health officer, aged 69, died, February 2, in Columbus, Ohio, of leukochemia.

Porter Morrison Wall, Monongahela, Pa., Western Pennsylvania Medical College, Pittsburgh, 1904, served during the Spanish American and World wars, aged 53, died, January 16, in Pittsburgh, of chronic arthritis.

John William Humphries, Culpeper, Va., George Washington University Medical School, Washington, D. C., 1906, member of the Medical Society of Virginia, aged 51, died, January 14, of heart disease.

Edward T. Printz, Moulton, Iowa, College of Physicians and Surgeons, Chicago, 1884, member of the Iowa State Medical Association, aged 74, died, January 12, of injuries received in an automobile accident.

Daniel T. Merritt, Nathalia, Va., University College of Medicine, Richmond, 1896, member of the Medical Society of Virginia, member of the school board, aged 61, died, January 19, of heart disease.

James Truman Reeves, Ferriday, La., Baltimore University School of Medicine, 1904, aged 53, died, January 14, in Natchez, Miss., of suffocation due to aortic aneurism pressing on the trachea.

John Quincey Holshfield, Tiptonville, Tenn., University of Tennessee College of Medicine, Memphis, 1919, aged 36, died, January 22, in the Baptist Hospital, Memphis, of pneumonia.

William B. Lyman, Boise, Idaho, Rush Medical College, Chicago, 1880, member of the Idaho State Medical Association, aged 75, died, Dec. 4, 1930, of myocarditis and coronary sclerosis.

George John Laben, Chicago, College of Physicians and Surgeons, Chicago, 1900, formerly served in the Indian Service, aged 62, died, January 14, of carcinoma of the urinary bladder.

Archibald Keightley, New York, University of Cambridge Faculty of Medicine, Cambridge, England, 1891, aged 71, died, Nov. 18, 1930, in St. Luke's Hospital, of angina pectoris.

John W. Gue, Caldwell, Idaho, Medical Department of Columbian University, Washington, D. C., 1894, aged 60, died, Dec. 26, 1930, in Boise, of arthritis and aplastic anemia.

Mark Hopkins Woolsey, San Francisco, Cooper Medical College, San Francisco, 1890, aged 64, died suddenly, January 28, of coronary sclerosis and occlusion.

Marie A Singletary, Denver Denver College of Medicine, 1898, Denver Homeopathic College, 1903 aged 75, died, Dec. 26, 1930, in St Luke's Hospital, of heart disease

Norton John Taylor, Berrinton, Kan., Penn Medical University, Philadelphia, 1865, member of the Kansas Medical Society, aged 88, died Dec 9, 1930, of cholecystitis

Ernst Jentzsch, Chicago, Bennett College of Eclectic Medicine and Surgery, 1901 aged 61 died, February 3, of myocarditis, chronic nephritis and diabetes mellitus

Martin L Harrell, Dallas, Texas, University of Nashville Medical Department, 1888, aged 69, died, Dec 6, 1930, of coronary thrombosis and pulmonary infarct

John H Moore ♂ Bridgeton, N J., University of Pennsylvania School of Medicine, Philadelphia, 1880, aged 75, died, January 2, in Maplewood, of heart disease

William Holt Worrell, Thomasville, Ga., Georgia College of Eclectic Medicine and Surgery, Atlanta, 1912, aged 48, died, January 16, of arteriosclerosis

John R Vinson, Callahan, Fla., Georgia College of Eclectic Medicine and Surgery, 1910, aged 45, died, January 9, in Leavenworth, Kan., of nephritis

Oscar H Fleming, Crestview, Fla. Atlanta Medical College, 1894, aged 62 died January 21, in a hospital at Florida, Ala., of intestinal obstruction

Edward B Mead, Sedalia, Ohio Starling Medical College, Columbus, 1888 formerly mayor of Sedalia, aged 70, died, January 21, of heart disease

Samuel F Price ♂ Jerome Idaho University of Michigan Medical School, Ann Arbor, 1891, aged 66, died, January 12, of streptococcal sore throat

Frances May McAdams, Bryan, Texas, University of Texas School of Medicine, Galveston, 1913, aged 45, died, January 6, of heart disease

Captain Hunter House, Atlanta, Ga. Georgia College of Eclectic Medicine and Surgery, Atlanta, 1907 aged 48, died, January 15, of pneumonia

Henry A Sutton, Marion Ind. Curtis Physio-Medical Institute Marion 1897, aged 83, died, January 19, of acute dilatation of the heart

Elmer J Taylor, Georgetown Ind. Kentucky School of Medicine, Louisville, 1902, aged 56 died, January 9, of acute pleurisy with effusion

William E Ryan, French Lick Ind. University of Louisville (Ky.) School of Medicine, 1882, aged 69, died, January 15, of arteriosclerosis

Adam T Mairs, Charleston W Va. College of Physicians and Surgeons, Baltimore, 1882, aged 74, died, January 10, of heart disease

Albert F Messner, Chicago, Hahnemann Medical College and Hospital, Chicago, 1890 aged 65, died January 18, of chronic myocarditis

William M Carter, Keokee, Va. (licensed Virginia by exemption), aged 66, died, Oct. 16, 1930, in Calvin, of cirrhosis of the liver

James B Jones, Garnett, Kan. (licensed Kansas 1901) Civil War veteran, aged 82, died, Dec 8, 1930, of carcinoma of the stomach

George Nathaniel Murphey, Paducah Ky., Kentucky School of Medicine, 1890, aged 78 died January 13, of heart disease

Minerva B Cushman, St Cloud Fla., Hering Medical College, Chicago, 1903, aged 74 died Oct 27, 1930 of heart disease

Sylvester A Broughman, Dayton Ohio Medical College of Ohio, Cincinnati, 1890 aged 73 died, January 18 of heart disease

Maximilian Pincus ♂ Chicago Jenner Medical College Chicago, 1908 aged 61, died January 25 of chronic myocarditis

Thomas A Finley, Rockville, Mo. (licensed Missouri 1883), aged 85 died January 18 of injuries received in a fall

Joseph C Shafer Noble Ill. Eclectic Medical Institute, Cincinnati 1907 aged 50 died January 19 of pneumonia

William G O Harra Los Angeles Chicago Medical College 1884 aged 71 died January 10 of heart disease

Charles H Fegers, Keokuk Iowa Keokuk Medical College 1895 aged 58 died January 19 of myocarditis

David L Weems Stark City Mo. Missouri Medical College St Louis 1882 aged 71 died Nov 30 1930

Bureau of Investigation

KOREMLU

A Dangerous Depilatory Containing Thallium Acetate

There has been on the market for some time a depilatory sold under the name of 'Koremlu Cream,' marketed first under the trade name 'Kora M Lublin,' more recently under the style 'Koremlu, Inc.," both of New York City. According to the advertising, Koremlu is "guaranteed to devitalize superfluous hair roots on face or any part of the body."

The preparation was first brought to the attention of the Bureau of Investigation by a Massachusetts physician, who sent in an article clipped from the *Boston Traveler*, published under the departmental title "Beauty—And How." The article purported to be by one V E Meadows, who was described as an "International Authority on Beauty." Meadows' article stated, in effect, that until recently, he had not been able to recommend any preparation for the removal of superfluous hair, but that he now was in a position to recommend a depilatory cream that would "not only remove hair, but devitalize the roots so that no more will grow." No mention was made in the article of Koremlu. A letter written to V E Meadows, however, asking for further information regarding the depilatory cream that he recommended brought the reply that it was Koremlu and advised the writer to get in touch with Kora M Lublin, who made it.

Soon after this, the Bureau of Investigation began getting inquiries regarding Koremlu and these have increased in frequency and number up to the present time. Some of these letters have reported that the Meadows person was on a 'lecture tour and was highly recommending Koremlu Cream. Among the letters thus received some contained hints and others definite statements that Koremlu had some thallium salt as its base.

The use of a thallium salt, in the form of acetate, as a therapeutic agent has been known for some years among dermatologists. It has also been known that thallium acetate is an extremely toxic substance. THE JOURNAL has reported many cases of death from thallium acetate poisoning when the substance had been given internally. As long ago as 1912, Dr. Sibouraud, a French authority on diseases of the hair and scalp, devised an ointment of thallium acetate for use in the removal of superfluous hair. Since that time, accidents have been reported from its use. Because of these accidents Sibouraud is said to have given up the method of using thallium for depilation purposes. The original Sibouraud prescription called for the introduction into the ointment of not over 1 per cent of thallium acetate. He repeatedly urged that even in this dosage one should use an amount of ointment not larger than two kernels of wheat, to be applied not more than once a day. Sibouraud has stated that if one uses an ointment containing a higher percentage or even applies an ointment having but 1 per cent of thallium acetate over any extended surfaces accidents may be expected. (See 'Paris Letter' JOURNAL A M A, January 18 1930).

It is equally well known by dermatologists that while thallium acetate whether taken internally or applied externally may result in complete baldness the condition is but temporary and the hair will return. Prof W E Dixon of Cambridge, who has done considerable experimental work with thallium salts, has brought out the fact developed experimentally that thallium induces a rapid growth of hair when administered to animals that have been shaved. He also reports that thallium salts exert no local action but when rubbed into the skin with oil or alcohol are readily absorbed and may produce systemic action. Incidentally the physiologic effect of ingesting thallium is mainly on the autonomic motor system, which becomes more sensitive so that electrical stimulation of nerves produces an exaggerated response.

Last November the Bureau of Investigation received an inquiry from a high-class department store in Baltimore asking for an expression of opinion regarding the possible dangers of Koremlu. The letter was written at the suggestion of Dr Charles R Austrian of that city. The Bureau of Investigation replied that Koremlu contained thallium that it is a

poisonous substance and mentioned the fact that there had been reported deaths from the therapeutic use of thallium compounds. There was further mentioned the fact that only a few weeks previously a letter had been received from a Baltimore physician regarding a patient who was acutely ill and who gave a history of having used Koremlu.

This reply to the request for information brought a week or two later a long letter from a firm of attorneys who stated that they had been retained by Koremlu Inc. to take action with reference to what were described as highly defamatory letters sent out by the Bureau of Investigation concerning Koremlu. The attorneys insisted that their client's preparation was not 'merely harmless but efficacious.' As a clinching argument they stated that the Health Department of the City of New York was entirely familiar with the product and its ingredients and had classed Koremlu simply as a cosmetic.

**and now those
UGLY HAIRS
can never
grow again!**

**A Written Guarantee assures the
permanent removal of unwanted hair**

THOUSANDS of women both here and abroad now know the joy of an alluringly smooth and beautiful skin free from the regrowth of ugly unwanted hair. The Koremlu Cream Method—the achievement of a noted French scientist—not only removes the hair for all time but actually is most beneficial to the skin itself.

Koremlu is a delightfully fragrant cream. You easily and quickly apply it to the hair like cold cream, and leave it on all night. The Koremlu Cream Method may be used with positive effectiveness on the face, legs, arms or any other part of the body.

The Koremlu Cream Method is guaranteed with

CREAM METHOD
of permanent
hair removal**

KOREMLU INC. 11 West 42nd St. New York

Reproduction (greatly reduced) of a column advertisement of Koremlu appearing in *Vogue* Feb. 1 1931

On November 6 *THE JOURNAL* received an inquiry from Dr. Milton Sherry of Baltimore regarding the ingredients of Koremlu. Dr. Sherry wrote in part:

Would you kindly let me know whether there is any lead or heavy metal present in this ointment which would produce a condition simulating lead poisoning with lead colic? The patient at the present time is acutely ill and an immediate answer would be greatly appreciated.

A few weeks later an interesting report appeared in the November 12 issue of the *Proceedings of the Staff Meetings of the Mayo Clinic*. It was entitled, 'A Case of Thallium Poisoning' by John Lansbury, M.D. The case was that of a woman of thirty-eight who was admitted to the Clinic with severe abdominal pain. The history was that five weeks before admission she started using Koremlu on her chin and upper lip. Two weeks later she was awakened one night with severe pains radiating across the thorax, a sense of constriction which made breathing difficult and sleeplessness. In the course of a few days the pain shifted to the lower extremities where it was felt mainly in the upper aspects of the thighs and the legs and toes. Later still she was seized with severe hypogastric pains accompanied by constant nausea and vomiting quite unrelated to food. At the time of admission she was doubled up with an intense abdominal pain, the breath was foul, the hair was loose and easily pulled out. A diagnosis of thallium poisoning was made. Five days after admission the patient was entirely

held except for a fringe of hair extending around the base of the skull above the ears. The eyebrows and eyelashes were not affected. Within two weeks, the texture of the skin had returned to normal and the hair was starting again to grow. The patient at that time complaining only of a peculiar feeling as though her legs did not belong to her. Dr. A. E. Osterberg of the Clinic analyzed the depilatory and reported it to contain a large amount of thallium. Another member of the Clinic staff, Dr. L. J. Birkles, found thallium in small amounts in the urine by spectroscopic examination.

On the same day that the Bureau of Investigation received the attorneys' letter from the Koremlu concern, it received a letter from Dr. Henry B. Potter of Walfield, R. I., enclosing a Koremlu circular and reporting an interesting case. To quote from the doctor's letter:

A woman came in to see me a short time ago with a jar of this ointment and an interesting history. She is of a masculine type strongly featured, has menstruated regularly every six months since puberty and has a strong beard (hard rather) that needed shaving every day. About three months ago she began rubbing this ointment into her face and her beard is almost gone, only a few fine hairs left on her chin. About two weeks ago her cranial hair began to come out rapidly and now she has not over a hundred hairs left. These hairs form a fringe at the rays of her neck and look as if their time is short.

On December 15, Dr. C. J. Noonan of Brooklyn, N. Y., wrote:

Have you any data on the constituents of the cream called Koremlu? I have a patient who has been using it on the lower limbs daily five months. She has developed a severe multiple neuritis of obscure origin.

On December 20, a dietitian connected with a hospital in Pennsylvania wrote:

I am interested in the cream known as Koremlu. People who are using it are experiencing pains appearing to be muscular in nature on the parts where this cream has been applied. Do you know the composition of it and can you give me any information which would prove or disprove that this product might be causing these pains?

In view of these reports and in spite of the fact that it was quite evident from information received from various sources that Koremlu contained thallium acetate, it seemed desirable for the information of the profession and the protection of the public that a detailed analysis of Koremlu be made and the Bureau of Investigation asked the A. M. A. Chemical Laboratory to make such an analysis. The Laboratory report follows:

LABORATORY REPORT

"An original jar of Koremlu Cream (Koremlu Inc. 11 West 42nd Street, New York City, price \$10.00) was submitted to the A. M. A. Chemical Laboratory for examination. The label on the jar bore the following statements: Koremlu Cream devitalizes superfluous hair roots. Will induce baldness wherever applied when used as directed."

The jar contained 69.8 Gm. (approximately 2½ ounces) of a light yellow ointment strongly perfumed. Qualitative tests indicated the presence of thallium, zinc acetate, petrolatum, trices or chloride and of saponifiable matter. Heavy metals (such as mercury, lead, arsenic and cadmium) sulphides, iodides, borates and silicates were not found. Quantitative determinations yielded the following:

Thallium (Tl*)	5.57 per cent
Zinc (Zn*)	7.68 per cent

"This may be calculated to

Thallium Acetate	7.18 per cent
Zinc oxide	9.56 per cent

"From the foregoing it is concluded that the product examined consists essentially of an ointment having a petrolatum base in which are incorporated approximately 7 per cent thallium acetate and 9.5 per cent zinc oxide."

In view of the chemists' report, it is again worth calling attention to the facts developed by Dr. Sabouraud. On the basis of long experience he declares that any ointment containing more than 1 per cent of thallium acetate is dangerous. Koremlu was found to contain over 7 per cent! Sabouraud insisted that no larger amount of his one per cent ointment than that equal to two kernels of wheat should be used at a time. No limit is given to the amount of Koremlu that should be applied! As the whole trend of the Koremlu advertising emphasizes that the stuff is harmless it is to be expected that women purchasing this product will apply it with the same

easy abandon that they use in applying face creams and vanishing creams. It is hard to believe that Kora M. Lublin, who seems to be behind this product, realizes the dangerous properties of the preparation she markets. It is kinder to assume that ignorance, rather than a callous disregard for public safety, prompts the sale of Koremlu!

There is one other point that seems to deserve some attention—that is, the wide discrepancy between the commercial value of Koremlu and its selling price. The approximate cost of the ingredients that go into a jar of Koremlu, selling at \$10, is less than thirty-five cents! This allows 27 cents for the thallium acetate, 1 cent for the zinc oxide and 4 cents for the petrolatum. However, Koremlu's assault on the public's pocketbook becomes a minor indictment, the major objection is its menace to the public health.

Correspondence

USE OF WHITMAN SPICA

To the Editor—In *THE JOURNAL* January 10 Dr. Walter I. Galland describes a "modified Whitman spica" for the treatment of fracture of the neck of the femur. In his opening paragraph Dr. Galland makes several statements which are so completely at variance with my own experience, and, I am sure, with that of every one who knows how to apply a plaster-of-paris spica bandage, that I am compelled to correct the impression the doctor creates, namely, that undesirable results attend the use of the ordinary or what Dr. Galland calls, a "full" spica. Dr. Galland says that

the application of a full spica extending from the ribs to the toes in an elderly patient is an expedient often fraught with serious consequences. On account of the dorsal decubitus which the spica necessitates plus the undue confinement of the costal cage with consequent diminution of the respiratory excursion the patient is exposed to the great danger of hypostatic pneumonia. Many patients who are treated for fracture of the neck of the femur in the classic spica succumb not to the fracture but to hypostasis in the pulmonary circulation.

In an experience that extends over a period of more than twenty years during which I have treated very many elderly patients with fractures of the hip, not only at the Hospital for Ruptured and Crippled but in several general hospitals, I have not had a single case of hypostatic pneumonia. This despite the fact that some of my patients were well over 80 years of age, and in one instance 93 years old. Dr. Galland's experience must indeed be unfortunate if "many patients treated in the classic spica succumb to hypostasis in the pulmonary circulation." I have been called to patients with fractured hips who had hypostatic pneumonia were suffering intensely and were in a deplorable state. But these patients were lying in bed without support and because of pain in the injured area could not be moved and were left in one position continuously.

Dr. Royal Whitman has repeatedly emphasized the need for proper protection of the body under any plaster dressing and for many years it has been the practice in treating a fracture of the hip to apply twelve layers of sheet cotton to the chest between the slurring and the plaster bandages. This provides a space of at least two inches and often more between the patient's skin and the plaster permits an expansion of the chest of at least four inches which is more than the average young adult has and surely more than the aged person has or needs and precludes any diminution of the respiratory excursion.

Dr. Galland further states that the spica necessitates dorsal decubitus. No such thing. One of the main advantages of a full plaster spica is that it permits free and frequent changes of position. A patient with a plaster spica can should and under proper treatment is turned on his face at least three times in the twenty-four hours and left in that position for at least an hour. In a well applied Whitman abduction spica there is nothing simpler than to turn the patient. I have often done it alone and my person nurse or attendant can be shown how to do it untroubled.

The primary requisite in the use of a plaster spica in the abduction treatment of a fracture of the hip is to appreciate every detail of the plaster technique. The skin should be thoroughly powdered. A smooth stockinet drawer extending from above the nipples to the toes is put on. The trunk and limb are enveloped in sheet cotton, twelve layers being used for the chest, from six to eight layers for the abdomen and pelvis, and from two to three for the thigh, leg and foot. A flannel bandage is then put on over the cotton, after which the plaster bandages are rolled on. The plaster is rubbed thoroughly to avoid wrinkles. When this dressing is completed there should not be, and there need not be any compression of any part of the body. On the contrary the plaster spica is a firm, smooth, comfortable support, completely relieving the patient of all pain.

The head of the bed should be raised on stilts from twelve to fifteen inches high. A fracture board must be inserted under the mattress to make the bed unyielding. Placed on this kind of a bed, the patient will be able to look about him and be entirely comfortable. The attendant should turn the patient on his face at least three times a day and the surgeon on his daily visit should put his hand under the plaster along the edges to make sure that there is no undue or unnecessary pressure.

There is no more comfortable or grateful patient than one with a fractured hip treated in a "competent" plaster-of-paris full spica bandage. Such a patient has plenty of room for breathing. He has frequent changes of position so that he does not get pulmonary hypostasis and does not die of hypostatic pneumonia.

SAMUEL KLEINBERG, M.D., New York

[NOTE—The letter of Dr. Kleinberg was referred to Dr. Galland who replies.]

To the Editor—It was not my purpose to belittle the importance or the wide applicability of the Whitman spica which I have used and which I feel I know how to apply. However, I do not think that the absolute comfort and safety of the elderly patient in the high spica is a universally accepted fact for I have observed that many physicians have difficulty in completely safeguarding such patients against the immobilizing effects of the high spica on the thorax. I have found the method of trimming, which I described to be both comfortable and effective, but I do not pretend that it is in any way a radical departure from the precepts of the Whitman method of treatment.

I agree with Dr. Kleinberg that my statement that the Whitman spica necessitates the dorsal decubitus is not entirely tenable as I well know the possibility of turning the patient in this spica. However, patients treated away from ample nursing facilities are frequently permitted to remain in the dorsal decubitus and the admonition that the patient be frequently turned is not always meticulously followed. Ability to free the costal cage more completely may at times be a desirable safeguard. It is obvious that if by a simple variation in the trimming of the plaster even a small measure of additional protection and comfort may be given to the patient without sacrificing the position of the fragments—one should certainly be privileged to vary slightly the classic spica of Dr. Whitman.

WALTER I. GALLAND, M.D., New York

FETUS PAPYRACEUS

To the Editor—In *Queries and Minor Notes* in a recent issue of *THE JOURNAL* (January 24, p. 291) under the heading, Complicated Twin Pregnancy, the following statement is made: A fetus papyraceus may also be found in the presence of triplets and in most of these instances two children are born alive and the third is a small compressed fetus. This I believe is not in accord with fact since in a review of the literature on the subject of papyraceous fetuses in triplet pregnancies (Beierlein K. M. *Am J Obst & Gynec* 21:97 [Jan.] 1931) I found twenty-one cases including one of my own or twin papyraceous fetuses as opposed to four cases of single

papyraceous fetuses in that connection. Since my paper was submitted for publication the number of reported cases in the first group has been augmented to twenty-two (Williams T M *Am J Obst & Gynec* 19 837 [June] 1930)

KARL M BEIERLEIN, M.D., Ann Arbor, Mich

"MISLEADING METHYL CHLORIDE PUBLICITY"

To the Editor—We have read your editorial "Misleading Methyl Chloride Publicity" (*THE JOURNAL*, January 24 p 272). Assuming that you present data to substantiate your criticisms it is, of course, your privilege to disagree with results that the Bureau of Mines may publish. However technical criticism is a different matter from indulging in such outbursts as that in your concluding paragraph.

"It is unfortunate that a branch of the government, the Bureau of Mines which has had such an enviable record in the past, has recently seemed to be swayed to serve more the interests of certain chemical manufacturers than to serve the interests of the public. It is laudible that the government should investigate general hazards to the public but it is quite unfortunate that independent action may be threatened by considerations arising from the fact that research is carried on under cooperative agreements."

For some years the Bureau of Mines has carried out investigations, through formal contracts with private individuals and private firms. They have gone to the Bureau of Mines presumably because of its experience, facilities and the integrity of its personnel. No one in the bureau is a penny the richer as the result of such work nor is the problem accepted unless it promises to produce information of value either to science, to industry, or to human welfare. The firm or individual submitting the problem pays the bill—as he should—but has no control over the prosecution of the work or of the results obtained.

With regard to the report on methyl chloride poisoning which you discuss, we wish to point out that you have ignored the earlier and much more extensive study of the compound which has already been published by the Bureau of Mines and in which the toxic properties of methyl chloride are fully described. Apparently you believe that the brief report on a single feature about which the Roessler & Hisslacher Chemical Company requested information, was the only one made.

We regard the series of papers from the Bureau of Mines—now appearing in *Public Health Reports*—on the toxicity of various new commercial solvents as an important contribution to industrial toxicology but not necessarily the final word. If you read these reports you will find the bureau has done a great deal more than search for "warning agents" which are not a guarantee of protection. Incidentally, your distinction between a toxic gas like ammonia which warns, and one to which a warning must be added, is subtle to say the least.

It seems to us that one of the important duties of the Bureau of Mines is to investigate the toxicity of new substances used in industry which may affect the public health. It represents an impartial agency for protection against hazardous advances made by industry. That its reports may be misrepresented in ill advised advertising is not a criticism of this bureau, but of the inability to control public misrepresentation. If the American Medical Association disagrees it would be more fitting for them to set up machinery to do the bureau's work than to make unsupported attacks upon the integrity of its personnel.

JOSEPH C AUB M.D. DAVID L EDWARDS M.D.
CECIL K DRINKER M.D. ALICE HAMILTON M.D.
PHILIP DRINKER CH.E. REID HUNT M.D.

NOTE—A careful rereading of the editorial in question should convince any one that its whole purpose is constructive. It does not attack the integrity of the personnel of the Bureau of Mines. It suggests merely the danger in a situation which may lay them open to such attacks.—Ed

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address but these will be omitted on request.

USE OF POTASSIUM THIOCYANATE IN HYPERTENSION

To the Editor—Please give data on potassium thiocyanate in essential hypertension. How does it act? What are the dangers and contra indications?

F R GRAZIER M.D. Yorkville Ill

ANSWER—The fact that thiocyanate resembled, even exceeded, the iodide ion in solvent action on aggregations of colloids suggested its trial in conditions analogous to those in which iodide has been found useful, and it indeed, seems to resemble iodide in its therapeutic as well as in its untoward effects, excepting in one notable respect: it does not affect the thyroid gland. In view of present inability to account satisfactorily for the effect of iodides on the circulation, in spite of extensive studies and the elaboration of several theories, none of which have found general acceptance, it is not to be wondered at that the action of thiocyanate which has been subject to much less study, can not as yet be satisfactorily explained. The reduction of blood pressure is dependent on the dose. The small dose of 0.1 Gm (1½ grains) three times daily frequently fails to produce an appreciable reduction. It also does not, as a rule, cause unpleasant by effects though such have been reported in the form of uncomfortable weakness, angular symptoms, exfoliative dermatitis and corvex. It is well to use such dosage initially to test the patient's tolerance. The large dose, 0.3 Gm (5 grains) three times a day reduces blood pressure in a majority of cases within several days or weeks, but it is so liable to cause untoward results that patients receiving these doses must be under careful supervision. Not only are they liable to complain of intolerable weakness chiefly in the arms and legs and of vertigo but, especially if the dose is increased to 0.6 Gm (10 grains) three times a day, a toxic psychosis may become superadded with disorientation, hallucinations, mania, confusion, and ideas of persecution lasting perhaps a week after discontinuance of the dosage. As these psychic disturbances are quite regularly preceded by the stage of weakness, it is advisable to discontinue the drug with its onset and to resume a smaller dose after the feeling of weakness has disappeared. Definite contraindications do not seem to have been worked out excepting that severe kidney damage increases tendency to intolerance. The Council on Pharmacy and Chemistry refused admission of potassium thiocyanate to New and Nonofficial Remedies because it considered the evidence for the drug's therapeutic value inconclusive and published a report stating the limitations of therapy with this drug (*THE JOURNAL*, June 1, 1929 p 1838).

CRANBERRIES AND DIGESTION

To the Editor—Please advise whether the organic acid content of a usual portion of cranberry sauce with an average meal is an aid to digestion and whether the cranberries act as a stimulus to gastric secretion?

M D Illinois

ANSWER—The organic acid content of an average portion of cranberries with the meal is not capable of materially or significantly changing the degree of acidity (pH) of the gastric contents in normal gastric digestion. Because of the relatively small quantity of citric acid that would be ingested and its low ionization, since it is a weak acid it would exert no practical buffering effect. Under normal conditions of gastric digestion the hydrochloric acid pepsin factor of safety is large. Any acidity change of the gastric content attributable to the cranberries would but slightly affect this factor.

Citric acid the chief organic acid of cranberries given in adequate quantities in gastric hypo-acidity would probably exert a favorable influence on gastric digestion. So far as is known from the literature, the effect of citric acid on gastric secretion has never been investigated.

To one fond of cranberry sauce its ingestion will certainly excite a psychic secretion of gastric juice this is known to be true for orange juice also. Cranberries however, do not contain secretagogues or chemical substances other than citric acid which may stimulate gastric secretion on introduction into the stomach. There is a probability that they may stimulate pancreatic secretion when in the intestine.

CHRONIC ENDOCERVICITIS DURING PREGNANCY

To the Editor—What measures can you suggest which may safely be used in the treatment of chronic endocervicitis (nongonorrheal) during the latter half of pregnancy? What is the liability of postpartum infection from this source? Kindly omit name
M D New York

ANSWER—If chronic endocervicitis does not produce annoying symptoms it is best left untreated during pregnancy. A few weeks after delivery it should be treated, chiefly by means of the electrical cautery. If, however, symptoms such as bleeding or profuse discharge occur during pregnancy, treatment should be instituted. Miller Martinez and Hodgdon (*THE JOURNAL*, Sept 27, 1930, p 923) favor the treatment of endocervicitis by means of cauterization during the first half of gestation even when there are no symptoms of the condition. They found erosions in 80 per cent of multiparas and in 10 per cent of primiparas. In a series of more than 2,000 cases in which the cervix was cauterized, only one abortion occurred. These authors maintain that this therapy is a prophylactic measure against puerperal sepsis rather than a contributing factor. In their series no case of sepsis occurred in women with healed cervixes, while during the same period two cases of severe sepsis occurred in cases in which the erosion was too extensive or lacerations too deep to allow successful cauterization. Temperatures were remarkably flat in contradistinction to the moderate elevations in the noncauterized group.

LEAKAGE OF FLUID DURING INJECTION OF VARICOSE VEINS

To the Editor—Recently I gave an injection of sodium salicylate for varicose veins. This was the sixth or seventh injection. It was given in the vein just below the popliteal artery and after the fluid was about half in the patient noticed a tremendous burning and stinging sensation over the middle of the lower third of the tibia right under the skin. In a day or two this became red much resembling a contusion and it became quite painful. This in a sense has healed and in a sense has not healed. The same soft contused looking type of a mass is about 3 inches above the original lesion. It seems to heal as it ascends and is constantly painful. Nothing seems to give much relief. The mass resembles more a squashed mulberry under the skin than anything else I know of. Anatomically I do not see what connection this could possibly have with the injection and I would be interested to know whether any similar condition is on record. The patient is not exactly mad about it but is disgusted and as the condition seems to heal it leaves pigmented spots which she would not mind if they were above the knees but it annoys her to have them below the knees.

LOUIS E. SHERMAN, M.D., Oakland, Calif.

ANSWER—The history of sudden burning and stinging at the time of injection means a leakage of the irritating sodium salicylate. The tissue necrosis following such leakage does not necessarily break through the skin but persists as a hard painful mass for a long time. The fact that such periphebitic patches are not at the site of injection but below it and above it means that there was a latent phlebitis and periphebitis present which became activated and now ascends in patches. The hemorrhagic exudate which follows the injection of highly irritating substances, such as sodium salicylate, absorbs with residual pigmentation. Concentration, amount of solution and constriction of the limb below and above the injection are important factors to bring about such leakage in particularly weak spots. If application of 30 per cent mercurial ointment and supportive measures do not bring relief, the excision of the entire segment by an experienced surgeon could be considered.

INDUSTRIAL HAZARD OF CHROMIC ACID

To the Editor—I am engaged in research involving electrolysis with chromic acid and am more or less exposed at times to the vapors arising from it. I am aware of the insidiousness of them and take precaution against them but I should like to know something of the physiologic and pathologic effects on the body and something of the treatment indicated. What is your opinion of sodium thiosulphate for counteracting the effects on the skin?
S. H. WILLIAMS, Creighton, Pa.

ANSWER—Industrial exposure to chromic acid chromates or bichromates may lead to the following related lesions:

1. A diffuse dermatitis usually on the hands and forearms.
2. 'Chrome holes'—single or multiple ulcerations of the skin and subcutaneous tissues ordinarily at the site of previous skin injuries.
3. Inflammation of the respiratory mucous membranes, with perforation of the nasal septum.

The diffuse dermatitis from chromium compounds is a simple chemical lesion which in the usual case tends to heal with or without treatment if exposure is not repeated. Secondary invasion by fungi may lead to a highly resistant condition.

Apparently, enough disinfectant properties of the chromium compound are retained in "chrome holes" to keep down infection, at least, frank bacterial invasion is not the rule. The inflammation of the respiratory tract may extend to the bronchioles, although it is usually limited to the nasal membranes. The septal perforation occurs at that point least supplied with blood in the area where squamous epithelium gives way to columnar. This area is in the line of the sweep of dusts and fumes taken in through inhalation.

Systemic disease from chromium is not a known result of industrial exposure. Its action is purely local. Just as little is known about the action of chromium compounds in tanning skins and hides, little is known about the state of the chromium compounds in their contact with human flesh. The action on tissues persists and spreads in spite of the usual efforts to arrest its progress. It is possible that chromic acid is changed into a chromate in the tissues and as such becomes fixed.

Those agents used in treatment are calculated to speed up reduction, with the formation of chromium hydroxide as the objective. This substance is less soluble and less irritating than the chromates. Sodium thiosulphate and ammonium polysulphide hasten reduction but, apparently, do not remove the chromium from the damaged tissues. Solutions of sodium bicarbonate, sodium citrate or potassium and sodium tritrate are stripping agents. It is stated that any one of these chemicals in weak solution, applied locally as wet dressings, tends to break down the chromium fixation in the tissues.

The spraying of mineral oil applications on mucous membranes provides a barrier, lessening the likelihood of harm from chromium fumes.

STATUS OF DICK SCARLET FEVER ANTITOXIN

To the Editor—A representative from E. R. Squibb and Sons was in my office today and made the statement that the Dick scarlet fever toxin was absolutely free from those substances which former scarlet fever toxins contained which produced damage to the heart muscles and to the kidneys. Will you kindly give me the present status of the Dick scarlet fever toxin relative to its safety as an immunizing agent against scarlet fever?
FORREST S. ETTER, M.D., Bartlesville, Okla.

ANSWER—The Dick scarlet fever toxin is regarded as a safe and efficient immunizing agent against scarlet fever. The main drawback to its use appears to be that several injections, generally not less than five, must be given before such a degree of immunity is established that the subject no longer gives a positive Dick test. The experience so far does not indicate that immunization with the toxin as practiced produces recognizable harm to the heart or the kidneys but to say that the toxin is "absolutely free" from injurious substances is of course going a little too far. Detail men should learn the value of understatement as compared with overstatement of what is known.

TREATMENT OF BONE TUBERCULOSIS

To the Editor—A man aged 30 years has had tuberculosis of the bone for the last fifteen years. It started with tuberculosis of the hip and gradually extended to the lumbar vertebrae. The active process healed though there is partial ankylosis in both regions. About five years ago he developed tuberculous arthritis of the right shoulder. (This was confirmed by guinea pig injection from the aspirated fluid of the joint.) Roentgenograms were taken at various intervals and the last one shows a progressive destructive arthritis involving the head of the humerus and the glenoid extremity of the scapula. At present there is limitation of motion and pain in the joint. A well known orthopedic surgeon advises surgical treatment by bone grafting thus producing ankylosis. Otherwise the surgeon states there may be a general spread of the disease and it may even result in pulmonary tuberculosis. Will you inform me whether or not an arthrodesis is the only treatment in this case or would complete rest of the joint in addition to physical therapy, heliotherapy and diet suffice? The patient is well nourished and otherwise well. Kindly omit name and address.
M.D. New York

ANSWER—Arthrodesis in a position of election is not the only treatment but it is the best. Complete rest of the joint in addition to heliotherapy, proper diet and hygiene may result in an ankylosis of the joint.

REMOVAL OF CORNS

To the Editor—A man aged 42 has been afflicted with recurrent corns (both soft and hard) on his small toe for three or four years. Salicylic acid locally in various combinations has proved futile. For the past eighteen months he has been treated by a chiropodist who cut the corns at periodic intervals. I would appreciate your opinion on the efficacy of the cautery (patient is not diabetic) and would welcome other suggestions. Please omit name.
M.D. New Jersey

ANSWER—The cautery is effective in removing both hard and soft corns. However, roentgen or radium therapy is preferred to the cautery.

CHILLINESS AND GOOSEFLESH BETWEEN
MENSTRUAL PERIODS

To the Editor—Kindly give me your opinion as to the cause and also suggestions for treatment of the following case. A woman aged 43 complains of extreme chilliness with waves of gooseflesh over her entire body about ten days before menstruation begins and sometimes during that period. Menstruation is otherwise normal. Do you consider these symptoms unusual? Please omit name and address.

MD Illinois

ANSWER—These symptoms are unusual and difficult to combat. It is generally believed that there is no definite effect exerted by menstruation on the body temperature. Some observers, however, hold that the temperature of the body is at its lowest midway between the menstrual periods and then gradually rises to a maximum about one or two days before the flow of blood begins. Other authorities maintain that the reverse is true. In the case cited a difference in body temperature about ten days before the onset of the menses may explain the chilliness. This difference can of course readily be detected, but even if there is a drop in temperature it may be difficult to prevent this. If there is a psychic factor in the sensations of chilliness and gooseflesh an attempt should be made to treat it.

O W LILL'S SOLUTION DENTAL

To the Editor—I have a patient who had prescribed for him by a dentist a preparation known as Lilly's Solution Dental made by the Lilly Dental Products Company of Welch W Va. The patient who used it noticed a dark discoloration of the tongue and teeth a few days after he began using it. Several days after its use was discontinued the discoloration disappeared. I will appreciate it if you will let me know what the ingredients of the solution are.

MD Roanoke Va

ANSWER—The A M A Chemical Laboratory reports that qualitative tests indicated the presence in relatively large amounts of mercury, iodide and an arsenic compound. The solution is alkaline to litmus. It is quite likely that the preparation contains potassium mercuric iodide and an arsenic compound such as "Solution of Potassium Arsenite U S P (Fowler's solution)." The product is apparently prepared by one Dr O W Lilly of Welch, W Va. It is recommended by the proprietor for Vincent's infection and all other acute, infectious ulcerative conditions of the gums and oral mucosa infected sockets and pyorrhea. It is a pity that a mixture of such potent ingredients may be dispensed under a proprietary name to the patient for pathologic conditions of the oral cavity. If a dentist or a physician desires to have his patient use a solution containing a mercury or an arsenic compound it should be prescribed according to the individual needs with full appreciation on the part of both prescriber and patient of its poisonous character.

MAILING OF LABORATORY SPECIMENS

To the Editor—After limited search I have been unable to find any information as to how to prepare for shipment different specimens for laboratory examination. Can you give me a reference where I may obtain such information? I am interested especially in (1) how to collect and prepare for shipment a specimen of spinal fluid for the complement fixation test for syphilis (2) a specimen of feces for culture for the typhoid bacillus (3) specimen of blood for culture for typhoid bacillus (4) material from the throat for examination for diphtheria (5) a blood smear for examination for malarial parasites.

— Michigan

ANSWER—In sending specimens for laboratory examination through the mail it is required that the postal clerks be not exposed to infection. To this end there has been included in the Postal Laws and Regulations section 473, specifications as to the preparation of certain specimens. These regulations have been somewhat modified in later years they may be found at any postoffice. There has been little published on this question since each laboratory has prepared mailing outfits in accordance with its own needs and the requirements of the postoffice department. The laboratory of each state health department will gladly supply additional information on request. If the specimens are to be sent by messenger instead of through the mails no special requirements are necessary.

1. Spinal fluid for the complement fixation test for syphilis can be sent in a sterile test tube enclosed in an ordinary cardboard mailing tube with a screw top. The same applies also to blood specimens for the Wassermann test.

2. Specimens of feces for culture for typhoid bacilli require a double mailing container the inside tube of tin and the outside of cardboard each with a screw top. The specimen should be mixed with glycerin or some other preservative which will not destroy the typhoid bacillus and yet will prevent the overgrowth of the colon bacillus.

3. Blood for culture for typhoid bacilli can be sent in a sterile glass test tube the same as for the Wassermann test, except that a double mailing container is required instead of a single mailing tube. In some laboratories, Kiedel tubes containing broth are used for this purpose. At any rate, the inside mailing tube must be of tin with plenty of cotton packing so that in case the glass tube is broken in transit the postal clerks will not be exposed to infection.

4. Throat cultures for examination for diphtheria, if sent on cotton swabs require the swab to be placed in a test tube and the test tube placed in a cardboard mailing tube with metal ends and screw top. If the specimen is swabbed on Loeffler's medium, this must be sent in a double mailing tube.

5. Blood smears for examination of malarial parasites can be made in the ordinary way and the microslides placed in a single cardboard mailing tube.

USE OF DIPHTHERIA TOXOID

To the Editor—Instructions coming with the preparations of diphtheria toxoid (kimon) prepared in this country suggest that it be used in children over 1 year of age and that results obtained in infants under 6 months of age are unsatisfactory. Is there any recent tabular evidence showing results obtained with toxoid in infants from 6 months to 1 year of age? As toxoid antitoxin mixtures require months to produce an active immunity and are usually not given until an infant is 6 months of age which method would give the better result—to refrain from using toxoid until the child is 1 year old and use antitoxin in cases of exposure or to use toxoid injections at the age of 6 months and attempt to develop an active immunity? If the latter what is the clinical evidence of the percentage of immunity developed?

MD Bessener MD Sheboygan Wi

ANSWER—As yet the statistics on results with toxoid in infants between 6 and 12 months of age are not sufficient to answer satisfactorily the questions asked. It should be noted that infants are relatively susceptible to diphtheria and consequently do not require urgently or as a rule to be immunized.

PARALYSIS OF SERRATUS MAGNUS

To the Editor—Can you give me information as to the nonsurgical treatment of a paralyzed serratus magnus muscle resulting in a winged scapula condition. Any citations to recent book or journal articles will also be appreciated as available references content themselves with a very poor prognosis unfavorable. Please omit name and address.

MD Ma achu etts

ANSWER—The nonsurgical treatment of a paralyzed serratus magnus muscle would be physical therapy, radiant heat, gentle massage, diathermy and the application of a brace to hold the shoulder in a backward position. The simplest splint for this purpose is the one described by R A Funston in THE JOURNAL, Sept 15 1928. Concerning references to operations, I would suggest the one by Schrock and Koenigs' operation described in Whitman's new book "A Treatise on Orthopaedic Surgery" published by Lea and Febiger, Philadelphia 1930.

RECURRENT DISLOCATION OF SHOULDER JOINT

To the Editor—A man aged 30 has a recurring subcoracoid dislocation of the right shoulder joint. Each successive dislocation has been more difficult to reduce. What prognosis may be given that an open operation on the joint will entirely correct this condition? Which operation would be the one of choice in this particular case? Have there been any new operations devised for this condition in the past three years? Please omit name.

MD

ANSWER—The prognosis in this condition is very good. The most generally accepted operation today is that designed by Henderson. This consists of a tenodesuspension from the acromion process to the head of the humerus using a piece of the peroneus longus tendon. In Henderson's last article which appeared in THE JOURNAL, Nov 29 1930 a bibliography is given.

UNTOWARD EFFECTS OF COID THIOSULPHATE

To the Editor—I have a patient to whom I have been giving gold thiosulphate 15 cc doses were given three times a week in conjunction with violet radiation. The patient is now complaining of an absolute loss of taste. I read an article in your magazine regarding this treatment for lupus vulgaris for which I have been using it and I am anxious to know whether this loss of taste is usual and if so is it a permanent condition.

A J LANGAN MD San Pedro Calif

ANSWER—Stomatitis is a rather common untoward effect of the treatment generally in association with an exanthem. A fairly extensive search of the literature failed to reveal mention of loss of taste sensation as an untoward effect. If this is due to the drug the probabilities are that in time the effect will disappear as do the other untoward actions of this agent.

Book Notices

METHODS AND PROBLEMS OF MEDICAL EDUCATION (EIGHTEENTH SERIES) Paper Pp 329, with 18 illustrations New York Rockefeller Foundation, 1930

This report consists of thirty-two articles written by men who represent leading schools of the United States, Canada, England, Wales, France, Germany, Denmark, Belgium, Yugoslavia, Argentina, India, Siam and South Africa Four of the articles are published in French, three in German and the remainder in English The report presents methods of instruction and teaching experiments with particular reference to physiology, biochemistry and physiologic chemistry and also tends to emphasize the role of the hospital and outpatient department as teaching units for undergraduate medical students The book is profusely illustrated with floor plans of the buildings described and photographs of the interiors and equipment In the foreign articles a summary is given of the history of medicine in the country, a description of the buildings, departments and equipment, an outline of departmental budgets and personnel, and detailed accounts of the curriculum The papers regarding American universities, in addition to historical data and building information, furnish comprehensive statements relative to instruction and opportunities for research Several special features in this report include methods for photographing gross pathologic specimens a description of the 'Heart Station' of the University of Michigan Hospital and one of the work and equipment of the Chevalier Jaelson Bronchoscopic Clinic, Temple University Hospital, Philadelphia The articles are all most interestingly written and the contents reveal a great deal of thought in preparation The report is unique in its scope, containing, as it does, material that is not available in general medical journals It gives one a splendid idea of comparative teaching methods here and abroad and is particularly recommended to officials of medical schools

THE EFFECT ON FOODS OF FUMIGATION WITH HYDROGEN CYANIDE By G W Monier Williams OBE, MC MA Reports on Public Health and Medical Subjects No 60 Ministry of Health Paper Price 6d Pp 32 London His Majesty's Stationery Office 1930

This covers the experience of the foods laboratory of the ministry of health and the work of others in connection with the retention of hydrogen cyanide in foodstuffs after the use of that substance for fumigation purposes While possessing no germicidal or fungicidal properties hydrogen cyanide is admirably suited to most of the requirements of an ideal fumigant for the destruction of rats moths weevils and other vermin and insects in such locations as the holds of ships It exerts no deleterious action on fabrics painted objects or metals is highly efficacious and is readily dispersed Three objections attend its use—the lack of a definite characteristic odor or other warning property its high toxicity for man and the domestic animals and its entry under some conditions into foods in amounts that may cause harm to the consumer or cause the decay of the food The amount of hydrogen cyanide constituting the threshold of danger to man cannot be fixed with definiteness As little as 10 mg per hundred grams of food is cited as a possible harmful quantity The author cites many instances of foods containing a higher amount of hydrogen cyanide than this possible minimum Dates figs honey, cocoa, bacon and sausages (all foods with a high moisture content), tested after having been aired twenty four hours after fumigation have proved to contain from 278 to 890 parts of hydrogen cyanide per million parts of air Fumigation by means of hydrogen cyanide carried out in excess of requirements particularly when used on fresh fruits or vegetables, may lead to commercial destruction or damage by interference with normal respiratory processes or by the modification of characteristic odor or tastes The dangers of hydrogen cyanide poisoning of foods stands in relation to the quantity of gas, the duration of application the moisture content of the foods the size of the particles or units of foods methods of packing and the period of ventilation after fumigation Foods treated with not more than 1 volume of hydrogen cyanide in 200 volumes of air, with subsequent exposure to the air do not usually contain more than 20 parts of the intoxicant per million of the food products

Computation of hydrogen cyanide concentrations in fumigation are usually reckoned in terms of the weight of the liquid or solid hydrogen cyanide per unit of space fumigated. This is in contrast to methods usually employed with some other liquid intoxicants (such as benzene) for which computations are based on parts of the gas formed on evaporation, having a vapor pressure equal to or under given conditions of temperature and barometric pressure. Relative toxicities are thus not always obvious in such terms as 'parts per million.'

The final estimate as to practical hazards entitled are indicated in the preliminary note by Sir George Newman, which says in part:

If the process is skillfully applied and due precautions are taken to prevent excessive absorption of gas, it would seem that no serious risk to health is likely to be involved. It must, however, be emphasized that indiscriminate treatment of food with hydrogen cyanide by inexperienced operators may be fraught with real danger to themselves and to the eventual consumer of the food.

This brochure is in excellent example of governmental research in health conservation, crying, while the interests of the commercial groups concerned and the public by frank recognition of the actuality of hazards in a much used process, and supplying limits within which safety is found to lie.

ARTIFICIAL SUNLIGHT COMBINING IRRADIATION FOR HEALTH WITH LIGHT FOR VISION. By M. Luckiesh, D.Sc., Director, Lighting Research Laboratory, Edison Lamp Works. Cloth. Price \$1.50. Pp. 254, with 73 illustrations. New York: D. Van Nostrand Company, Inc. 1928.

The director of a large industrial research laboratory has presented in this nonmathematical book an interesting and understandable thesis on the physical properties of light. It seems to be the most complete source of information on this subject now available. Concerned largely with the biologic and therapeutic values of light, the book endeavors to lay a foundation that will inaugurate a new era of dual-purpose lighting by combining radiant health-giving energy with light for vision. It contains excellent diagrams, curves and tables that present in abundance of statistics. The author's point of emphasis is the health-maintaining value of radiant energy in addition to lighting for vision. He presents this logically by devoting a chapter to the sun's beneficial effects and calling attention to the research of Nils Finson and Auguste Rollier. This is undoubtedly one of the most extensive accumulations of facts on solar radiation that has been assembled. The author pleads for an orderly standardization of units for use in light therapy. This important step should receive careful attention. The medical profession needs a dosage unit and a method to measure it for administering light therapy. A correct and scientific method of arriving at a therapeutic unit is to standardize the physical unit. Evidently Dr. Luckiesh is following one of many leads to aid science in accomplishing this purpose. He points out that the erythema basis is a sound method of approach. The paragraphs devoted to the erythema-producing, germicidal and curative properties of light are extensive. For those who are interested in ultraviolet measurement much information is presented in the chapter on measurements of ultraviolet radiation. Various ultraviolet reflectors are described; the most efficient appear to be those finished with dull black paint. At first this fact seems odd, since visible light is reflected much better by shiny surfaces such as silver, enamel and zinc oxide. If dual-purpose lighting becomes popular, revolutionary methods in the art of reflecting light must be developed. An excellent chapter on the ultraviolet transmitting mediums is compiled and the author refers freely to many investigators and their research. The curative value of long wavelength radiations is discussed in a chapter on infrared radiations. This valuable agent is important in heating body tissues and relieving pain and the author notes that infrared, or heat radiations have never been exploited as extensively as the ultraviolet. Although this book is a veiled advertisement for the General Electric S-1 Sunlamp, physicians with an investigative turn of mind and desirous of the truth will find the information surprisingly unbiased. The book fills an urgent need in the general practice of light therapy. Further scientific information is needed to warrant the extra expenditure for installing dual-purpose lighting. Future evidence may substantiate Dr. Luckiesh's propaganda in laying this foundation. It is doubted, however, that the sun will ever be seriously challenged.

LES TOIS CARDIALES DE LA DISTRIBUTION ET DU METABOLISME DE L'ALCOOL ETHYLIQUE DANS L'ORGANISME HUMAIN. Par Erik M. P. Widmark. De l'Institut de chimie medicale de l'Université de Lund. Pp. 57, with 43 illustrations. Lund: C. W. K. Gleerup. 1928.

The alcohol question has occupied the minds of men since the dawn of history. The writers of the old and the new testament were impressed with its social importance. Social aspects in our day are no less important than they were in those days, but the political aspect has overshadowed the scientific aspect, on which all sound legislation should rest. It is even more incomprehensible that those who have the necessary scientific training to evaluate properly the use and the abuse of the article have been carried away with fury created by politicians and self-appointed reformers. Because of this importance, many scientific studies have been made on the rate of alcohol in the human economy. In limited amounts it may serve as a source of energy, is not disputed even by the most rabid opponents to its social use. Its abuses are too well known. The thought behind the present study by Protes or Widmark was to throw light on the frequently observed phenomenon that different individuals show different degrees of intoxication by ingestion of the same amount of alcohol. He starts out to answer two general questions: 1. In what measure can the same amount of alcohol result in a variable concentration of alcohol in the blood and consequently in tissues sensitive to it? 2. Can the same concentration of alcohol produce a different degree of intoxication within different individuals? The pamphlet contains an account of an address delivered in April 1920 and presents the results of an attempt to evaluate each of the special factors such as weight and condition of the body and metabolism factor the concentration in the blood after ingestion and so on by a series of apparently carefully controlled experiments. The author arrives at a general formula of possible interest in forensic medicine by which the amount of alcohol ingested can be determined within reasonable limits some time after ingestion if only two known factors are at hand—body weight and concentration of the blood. The importance of this is Professor Widmark sees it is a measure of the degree of intoxication. This investigation represents an important addition to an already large literature on alcohol and may profitably be read by students of the scientific aspects of the alcohol question.

THE AFRICAN REPUBLIC OF LIBERIA AND THE LIBERIA CONGO PAST AND THE ORIGIN OF A MALE AND MATERIAL COLLECTED DURING THE HARVARD AFRICAN EXPEDITION 1926-1927. Edited by Richard I. Strong. Volumes I and II. Cloth. Price \$15 per set. Pp. 1064, with illustrations. Cambridge: Harvard University Press. 1928.

Harvard University sent an expedition into Africa in 1926 and 1927 to make a biologic and medical survey of Liberia. The expedition was under the direction of Dr. Richard I. Strong, professor of tropical medicine, with whom seven other professors and assistants were associated. A survey of diseases present in the interior of Liberia had not previously been made. In these two volumes is the story of the travels of the expedition back and forth across Liberia and reports of the diseases found that affect the inhabitants, animals and plants. There are many instructive pictures of diseases, some colored plates of microscopic observations, pictures showing the circumstances under which these people live and maps illustrating the routes the expedition followed. Aside from their value to the sciences the two volumes will entertain and instruct any one interested in distant places.

ACCIDENTES OCULARES DEL TRABAJO EN EL URUGUAY. Por el Dr. Dr. Enrique Mender. Medico Oculista del Banco de Seguro del Estado. Congreso Medico del Centenario. Seccional de Oftalmologia. Paper. Pp. 22. Montevideo: Congreso Medico del Centenario. 1910.

In Uruguay in the years 1914 to 1929 6,228 ocular injuries were recorded. Almost two thirds of these were caused by impaction of foreign bodies while contusions and burns hold second and third places. In more recent years these traumatic lesions have been more frequent and it is interesting to note that the left eye is more often affected. A satisfactory explanation of this fact is not given. The author warns against malingerers and concludes his well formulated statistical report with the suggestion that efficient prophylaxis be practiced to protect workmen.

DISEASES OF THE GENITO URINARY SYSTEM IN INFANCY AND CHILDHOOD By Henry T. Helmholtz M.D. Professor of Pediatrics University of Minnesota (The Mayo Foundation) and Samuel Amberg M.D. Associate Professor of Pediatrics, University of Minnesota (The Mayo Foundation) Supervising editor Royal Storrs Haynes Ph.D. M.D., Clinical Professor of Diseases of Children College of Physicians and Surgeons Columbia University. Volume VII. Clinical Pediatrics. Cloth. Price, \$85 per set of 21 volumes (sold only in set). Pp. 209 with 27 illustrations. New York: D. Appleton & Company 1930.

Writers who grapple with renal disease display literary heroism. The classification is becoming a matter of keener and keener controversy in light of the recent advances in blood chemistry, renal function tests and data concerning edema. When urinary disturbances such as enuresis, diagnostic considerations and the details of genito urinary involvement are added the writers of a monograph have ample reason to be daunted. The authors of this volume have simplified the subject as only authorities may. Beginning with chapters on embryology, anatomy, physiology and diagnostic methods, they proceed with urinary disorders, renal disease, pyogenic infections of the urinary tract and diseases of the kidney and bladder concluding with considerations of the anomalies and diseases of the male and female generative tracts. Where embryologic diagrams clarify the abstract, embryologic diagrams are offered. Where roentgenograms are diagnostic such reproductions are displayed. Where diets are pertinent, detailed diets are tabulated. There is an unmistakable note of rich personal experience both in the text and in the typical text cases described. This book was apparently slightly too early for experience with the urinary dyes but the omission has not proved an insurmountable handicap to the authors with their facilities and determination to diagnose. It would be inaccurate to state that volumes of information have been compressed within these few pages. There is never the impression of a hasty short cut or a view of high lights, compend fashion. Rather one appreciates that the vast literature has been painstakingly sifted so that only seasoned facts are included. Keen discrimination throws searchlights on the essential, whether the spectacular nephrosis or the garden variety of hemorrhagic nephritis. The work has the analytic, authoritative lecture note of a professor of the fundamental sciences speaking clinically.

SOZIALE KRANKHEIT UND SOZIALE GESUNDHEIT Von Dr. Viktor Weissweiler o. Professor an der Universität Heidelberg. Paper. Price 2.80 marks. Pp. 52. Berlin: Julius Springer 1930.

This pamphlet was written to clear up the relation between the physician and the individual whose working capacity is really or supposedly impaired. This is important in Germany where thirteen million working people rely on subvention furnished by public money. Six million of these must be professionally examined in order to determine the correctness and amount of their claims. The author discusses the question whether there is a system of pathologic recognition that enables the examiner to determine satisfactorily the earning faculty of the individual and he denies such a possibility. The pathologic recognition determines the nature of the disease but not the quality of the remaining health and the working capacity of the residual functions. Great stress is laid on the investigation and improvement of the mental condition of the patient. At present it is impossible to draw from the status of morbidity definite conclusions for the determination of the functional capacity of the individual concerned. It will be the task of the physicians to develop methods for the gauging of the working capabilities. As a basis for this endeavor the question of true incapability for work, the mental disposition toward labor, and the lack of occupation though the willingness to work must be considered. This pamphlet will be of great interest to everybody who has to deal with industrial compensation work.

MOTHER ALPHONSA ROSE HAWTHORNE LATHROP By James J. Walsh M.D. Ph.D. Cloth. Price \$2.25. Pp. 147 with illustrations. New York: Macmillan Company 1930.

In 1894 the younger daughter of Nathaniel Hawthorne Rose Hawthorne Lathrop located in a three room flat on the lower east side of New York in order to help the poor who were suffering from incurable cancer. She took a few patients to live in the apartment with her recurred others into her home in order to dress their lesions and visited many more in their

own homes. Such was the beginning of a work that filled the remainder of her life. This book is the story of her service. Mrs. Lathrop's hope that her work would extend to other cities is being partially realized at present with the opening in Philadelphia of a similar home. The author writes of Mother Alphonsa from knowledge gained by association with her in this work. He also includes parts of Mother Alphonsa's diary and letters. Nathaniel Hawthorne, her father, visited in this home, as did other members of that noted family. In these pages is a charming description of Nathaniel Hawthorne's early home life during the trying years before he had written anything notable. The devotion of the Hawthornes reminds one of the Brownings of England. It was natural, therefore that their daughter should devote her life to the service of others.

DIE VISCEROGRAFISCHE METHODE. MENSCHLICHE NORMALE UND PATHOLOGISCHE PHYSIOLOGIE UND PHARMAKODYNAMIE DER MOTILITÄT DES OESOPHAGUS, DES MAGENS, DES DARMS UND DER BLASE. Von D. Danielopolu. Professor der medizinischen Klinik an der Universität und Direktor des medizinisch-klinischen Institutes B im Fildertropfen-Spital in Bukarest. Paper. Price 7.20 marks. Pp. 166 with 130 illustrations. Berlin: S. Karger 1930.

This is a compilation of work published during the last ten years by the author and his collaborators. It consists of physiologic and pharmacologic experiments on normal and diseased men. In these experiments, from one to three recording balloons were passed into the esophagus, stomach, small intestine, colon or bladder. Danielopolu believes that this type of work is of great value to the clinician, but in the rather verbose discussion of the experiments he does not present much to support the statement. He feels that his experiments are of great value also in showing how different the pharmacologic reactions of the digestive tract are in man and in laboratory animals. Actually, the kymographic records show that drugs act much the same in animals and in man. The striking fact which the clinician should note is that most of the actions of drugs were fleeting. The physician, when he gives a drug, hopes to secure an action that will last several hours; Danielopolu's records show that the effect usually lasts seconds or minutes; it is often a mixture of inhibition and stimulation and this mixture varies with the dosage used. The book really constitutes a valuable and unusual contribution to the knowledge of the motor functions of the digestive tract. There is much of interest about the behavior of the esophagus, stomach and bowel. It is interesting to see that atropine and physostigmine appear to sensitize the gastric musculature so that it will react more markedly to psychic stimuli. The esophagus in cases of cardiospasm appears to contract peculiarly. Large doses of ephedrine appear to quiet the intestine for several minutes. Pilocarpine produced a temporary increase of gastric motility followed by a period of quiet. The effect of ephedrine lasted only a few seconds. Small doses of atropine seemed to increase the activity of the stomach but large ones inhibited it. The book should be studied by every one who is interested in the research side of gastroenterology.

OPERATIVE CYNECOLOGY By Harry Sturgeon Crossen M.D. F.A.C.S. Professor of Clinical Gynecology, Washington University School of Medicine and Robert James Crossen M.D. Instructor in Clinical Gynecology and Obstetrics, Washington University School of Medicine. Fourth edition. Cloth. Price \$15. Pp. 1075 with 1248 illustrations. St. Louis: C. V. Mosby Company 1930.

The present edition of this popular book which was revised with the assistance of the younger Crossen is much larger than any of the previous editions. The first edition had 677 pages and 887 illustrations. The general plan of the book is essentially the same. The new illustrations are just as instructive as the old ones and the increased space devoted to descriptions of operations is commendable. However it seems unnecessary to devote eighty pages and ninety-five illustrations to retrodisplacement of the uterus for less and less importance is being attached to uncomplicated retroversion of the uterus. Whereas the 1925 edition did not cover such important matters as anesthesia and internal surgery which may be associated with pelvic operations, the present volume contains instructive and beautifully illustrated chapters on these subjects. The detailed description and illustrations of the use of local anesthesia are especially praiseworthy. Special extensive chapters are now devoted to genital fistulas and to the urinary tract in

relation to pelvic surgery. There is also a thorough discussion of radiation therapy. The present volume, like its predecessors will undoubtedly continue to be a popular book, but \$15 is rather a high price for a single volume.

Medicolegal

A Nurse as Employee or Independent Contractor

(*Renoif v. New York Central & Co. (N. Y.) 240 N. Y. S. 710*)

A surgeon for the New York Central Railroad Company sent an injured employee of the company to a private hospital instructing the hospital to assign private nurses to the patient. It was conceded that in doing so he was acting within the scope of his authority as an agent for the railroad. The claimant was a special nurse so assigned. Her orders came from the physician who employed her on behalf of the railroad company. The company paid her through the hospital as its agent. In the course of her employment she pricked her finger, infection followed and the finger had to be amputated. From an award of compensation against the railroad company the company appealed to the Supreme Court of New York Appellate Division, Third Department.

Counsel for the insurance carrier evidently contended that a nurse like a physician is engaged in an independent calling and that neither can become the servant of another. This argument said the Supreme Court is fallacious. Ordinarily the relation of master and servant does not exist between a person engaged in the practice of a profession and a person who engages him for a limited purpose or transaction. There is no reason, however, why that relation cannot be created. Frequently lawyers, doctors and other men of skill are employed at regular salaries for definite periods. Such contracts of employment create the relation of master and servant. *Greenberg v. Jerome H. Remick & Co.*, 230 N. Y. 70, 75, 129 N. E. 211. The relation may be created by contract, either express or implied. *Brown v. St. Vincent's Hospital*, 222 App. Div. 402, 226 N. Y. S. 317. Whether or not the relation exists may be tested by the right of the employer to control or direct the work of the employee, the payment of wages and the right to hire and discharge. In the present case, it was conceded that the railroad company gave its physician authority to select employees, whose salaries the company paid. The nurse to whom compensation was awarded was so employed and paid. She was subject to the orders of the physician and could be discharged by him. She was the employee of the railroad company just the same as though she had been employed in the company's own emergency hospital. There is no difference between this case and one wherein a superintendent is authorized to employ an expert mechanic for a limited time to render some special service in repairing a locomotive. The award was accordingly affirmed.

Gonorrheal Infection of Eyes an Accident

(*McFarland v. Massachusetts Bonding & Ins. Co. (Tenn.)* 76 S. W. (2d) 159)

The plaintiff sued the defendant insurance company on a policy insuring him 'against disability resulting directly, and independently of all other causes, from bodily injuries sustained through external, violent and accidental means.' It was stipulated by the parties that an oculist whom the plaintiff consulted found gonococci in his eyes, that the plaintiff did not know the exact time and place when the gonococci entered and did not know of their presence until inflammation set in, that they entered without his knowledge or consent, that neither when inflammation set in nor at any other time was the plaintiff afflicted with gonorrhea and that until his eyes became inflamed he had never knowingly had gonococci in his body. It was further stipulated that gonococci could be introduced into the eye by rubbing with the finger or hand or with an infected cloth. In the trial court, judgment was entered for the plaintiff and the insurer appealed to the Supreme Court of Tennessee.

The insurer contended that the unexplained presence of gonococci in the plaintiff's eyes did not justify the conclusion of the trial court that the injury was the result of external violent and accidental means. Within the terms of the policy, the

insurer contended the means through which the injury is effected must be accidental, not merely the injury itself. If a condition is produced by a voluntary act which is executed as intended but results in unknown, unforeseen, unexpected and unintended consequences it is not, argued the insurer, sustained through 'accidental means,' within the terms of the policy. Under this contention, if the eye was rubbed with the finger, hand or a glove infected with gonococci without the knowledge of the insured the infection would be due to a voluntary act, executed as intended and would not be accidental. On the other hand if on the street the wind blew the gonococci into the eye so that they became impacted and embedded, the means of getting the gonococci into the eyes would be accidental and the injury therefore accidental.

The mind yields reluctantly said the Supreme Court, to the conclusion that pathogenic bacteria are autopropagules capable of acts of violence that produce, not disease but accidental injury. That conclusion however seemed to the court to be well supported by authorities cited in the opinion rendered when this case was before the court on a previous occasion. *McFarland v. Massachusetts Bonding & Ins. Co.* 157 Tenn. 254, 8 S. W. (2d) 369, 370. The contention of the insurer presents a dilemma. If it is an accident when the germ comes from space and strikes the victim, what is it when the germ crawls from the hand or an object in the hand and digs in? The Supreme Court was unable to agree with the contention of the insurer that the latter method of infection would not be an accident within the meaning of the policy. When the injury is proved and shown to have been through external and violent means and the Supreme Court citing from its previous opinion and it appears that it was not intentionally inflicted, the requirements of the policy are sufficiently met unless it appears that it was the natural result of some voluntary act of the insured.

The judgment of the court below, in favor of the insured, was affirmed.

Evidence—Statements by Patient to Physician, When Admissible.—A physician may testify as to statements made by a patient relating to the patient's condition at the time of an examination or treatment. The opinion of a physician, however, based on a history of events or circumstances as to how an injury occurred related to him by a patient is inadmissible in evidence. *Mendenhall v. Springfield Traction Co. (Mo.)* 26 S. W. (2d) 30.

Society Proceedings

COMING MEETINGS

- American Association for the Study of Gout, Kansas City, Mo. April 7-9. Dr. J. R. Yung, 670 Cherry Street, Terre Haute, Ind., Secretary.
- American Association of Anatomists, Chicago, April 2-4. Dr. George W. Corner, University of Rochester School of Medicine, Rochester, N. Y., Secretary.
- American Association of Pathologists and Bacteriologists, Cleveland, April 2-3. Dr. H. T. Karsner, 2085 Adelbert Road, Cleveland, Secy.
- American College of Physicians, Baltimore, March 23-27. Mr. E. R. Loveland, 155 South 36th Street, Philadelphia, Executive Secretary.
- American Orthopedic Association, Memphis, Tennessee, April 15-18. Dr. DeForest P. Willard, 1916 Spruce Street, Philadelphia, Secretary.
- American Pediatric Society, Edgewater Park, Mississippi, April 15-17. Dr. H. C. Carpenter, 1805 Spruce Street, Philadelphia, Secretary.
- American Physiological Society, Montreal, April 8-11. Dr. Arno B. Luckhardt, 5216 Greenwood Avenue, Chicago, Secretary.
- American Society for Experimental Pathology, Montreal, April 8-11. Dr. C. Philip Miller, Jr., University of Chicago, Department of Medicine, Chicago, Secretary.
- American Society for Pharmacology and Experimental Therapeutics, Montreal, April 8-11. Dr. E. D. Brown, University of Minnesota, Medical School, Minneapolis, Secretary.
- American Society of Biological Chemistry, Montreal, April 9-11. Dr. H. B. Lewis, University of Michigan, Medical School, Ann Arbor, Mich., Secretary.
- Federation of American Societies for Experimental Biology, Montreal, April 8-11. Dr. H. B. Lewis, University of Michigan, Medical School, Ann Arbor, Mich., Secretary.
- Louisiana State Medical Society, New Orleans, April 14-16. Dr. I. F. Talbot, 1430 Tulane Avenue, New Orleans, Secretary.
- Pacific Coast Surgical Association, Victoria, British Columbia, February 27-29. Dr. E. F. Cilestree, 384 Post Street, San Francisco, Secretary.
- Southeastern Surgical Congress, Atlanta, Ga., March 9-10. Dr. B. T. Leasley, 45 Edgewood Ave., Atlanta, Ga., Secretary.
- Tennessee State Medical Association, Knoxville, April 14-16. Dr. H. H. Shoulders, 706 Church Street, Nashville, Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL in continental United States and Canada for a period of three days. Issues of periodicals are kept on file for a period of five years only. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Rasmussen Minneapolis—p. 461

Sexual Cycle in Birds. Normal Regressive Changes in Testis of European Starling (*Sturnus Vulgaris*) from May to November T. H.
Bissonnette Hartford, Conn.—p. 477

Basophilic Cells in Posterior Lobe of Human Hypophysis—A histologic study of fresh normal adult human hypophyses has been made by Rasmussen for the purpose of throwing further light on the origin of the basophilic cells that invade the posterior lobe. It appears that pars intermedia cells both in the main stratum which forms the posterior wall of the cleft and in the strands and tubules which grow backward from it may become strongly basophilic and assume the general characteristics of basophilic cells of the anterior lobe. This transition does not involve an acidophilic stage. Only an occasional isolated acidophilic cell is found in the pars intermedia. This suggests that the basophilic cells are not derived from the acidophilic type, at least under certain conditions. If these basophilic cells are of the same type as the basophils found in the anterior lobe, the clear (or slightly basophilic) cells of the pars intermedia might be looked on as undeveloped cells almost exclusively of the basophilic type. While the possibility of migration of cells from the anterior lobe into the posterior lobe is not denied, it is certainly evident that abundant cells from the pars intermedia may become strongly basophilic and in some instances, at least, account for the great number of basophilic cells that invade the nervous lobe.

Traumatic Rupture of Diaphragm C. C. I. Wheatley New Haven
Conn.—p. 670

Diverticulum of Duodenum Perforated into Pancreas C. C. I.—p. 684

Roentgen Diagnosis of Chronic Appendicitis—In a routine study made by Walton and Weinstein of 1000 consecutive gastro-intestinal examinations there was roentgen evidence of a pathologic appendix in 152 instances, or 15.2 per cent. This diagnosis was confirmed either clinically or at operation in 133 cases, or 87.5 per cent. The incidence of appendicitis was noted to be greatest between the ages of 20 and 50 years.

Tissue Reaction to Irradiation Segment of Growing Mouse Tail as Biologic Indicator—Bagg and Halter assert that a 5 to 7 mm segment of the tail of a young mouse (approximately 9 to 12 mm of tissue) can be used to advantage as a measure of the biologic effects of irradiation. The degree of the effect of irradiation may be measured in terms of disturbance of epilation, in retardation in the growth of the tail, or in the spontaneous amputation reaction.

Blood Changes in Leukemias and Lymphomas and Bearing on Roentgen Therapy—Isaacs asserts that roentgen irradiation stimulates primitive myeloblasts and lymphoblasts to rapid reproduction. Myelocytes and small lymphocytes are stimulated to finish their life history and they then die or are excreted. The latent period between the exposure to irradiation and the elimination of the leucocytes represents the period of maturation and development of the individual cells to senility. The matured cells are excreted into the gastro-intestinal tract (polymorphonuclear cells into the mouth, lymphocytes into the intestine). Very rapid excretion may result in a decrease in the number of cells in the peripheral circulation (leukopenia), giving the false impression of an aplastic bone marrow. Anemia may mean crowding out of red blood cell tissue by foreign cells or it may mean actual aplasia of the bone marrow. Anemia, then, as well as leukopenia, may not necessarily be a contraindication to roentgen therapy. As the peripheral blood count does not always give a clue to the state of the blood-forming organs, several other factors must be taken into account in considering treatment (rate of cell destruction, type of the cells, basal metabolic rate and associated symptoms and previous response to roentgen irradiation).

Roentgen Treatment of Metastasis from Carcinoma of Breast—Metastasis from carcinoma of the breast reaches the pelvic and vertebral bones, probably by a combination of aberrant and reflux spreads through the lymphatics, and is often accompanied by an inflammatory reaction of noninfectious origin. The most common symptom of such lesions is pain in the right sciatic nerve. The distribution and type of metastasis in the group studied by Leddy bore no relationship to the primary tumor. Treatment by roentgen rays by an effect on both the inflammatory and the malignant cells in the metastatic growths produces analgesia, often complete and of months' duration, and is the best method of palliating a hopeless disease.

High Voltage Roentgen Therapy of Mammary Carcinoma—Five years of experience with many cases has convinced Evans and Leucutia that roentgen therapy in its short wavelength application is of considerable aid in treatment of operable mammary carcinoma as an auxiliary to surgical procedures. Whereas, in the cases without glandular involvement the addition of irradiation does not seem noticeably to increase the five-year results above those of surgery alone assuming, of course, that all the diseased tissues were removed in the carcinomas that had already spread to the axillary or the high thoracic lymph nodes the five year results are nearly doubled. The best method of procedure is a combination of radical surgery with a thorough systematic irradiation of the entire anterior thorax, axilla and neck on the diseased side. In the inoperable or recurrent mammary carcinomas roentgen therapy produces prolongation of life if the lesion is localized to the adjacent lymph nodes or anterior thorax and alleviates the symptoms if the carcinoma is already generalized.

Significance of Certain Ophthalmoscopic Pictures in Hypertensive Diseases.—In 274 cases of hypertensive and renal diseases the ophthalmoscopic observations were studied by Fishberg and Oppenheimer in relation to the clinical picture. In thirty-nine of the cases, postmortem observations also were made. The concept of albuminuric retinitis includes three distinct pathogenic entities which can most often be differentiated with the ophthalmoscope: (a) arteriosclerotic retinopathy, (b) malignant hypertensive neuroretinitis and (c) choked disk due to increased intracranial tension from edema of the brain. The ophthalmoscopic characteristics of these three types of retinal changes are described and their occurrence and prognostic significance in the individual types of hypertensive disease investigated. In all of the ten cases of essential hypertension with malignant hypertensive neuroretinitis in which the patients came to necropsy, necrosis of the renal arterioles was present. On the other hand, necrosis of the renal arterioles was absent in eleven instances of essential hypertension without malignant hypertensive neuroretinitis that were studied at necropsy. Instances are described of malignant hypertensive neuroretinitis in a patient with arterial hypertension due to suprarenal tumor and of arteriosclerotic retinopathy accompanying hypertension resulting from amyloid contracted kidney.

Does Climate Affect the Human Conception Rate?—The birth statistics of different cities, states and countries were analyzed by Mills and Senior and it was found that human fertility, as indicated by the conception rate, is highest in any given population at a temperature of about 65 F. and that it is reduced during the low temperatures of the northern winter and by mean summer temperatures above 70 F. The summer depression is roughly proportional to the rise in the mean temperature above 70 F. These changes in conception rate are not dependent on changes in the marriage rate or sexual activity of the population and must therefore represent actual variations in human fertility.

Thyrotoxicosis Following Subtotal Thyroidectomy for Exophthalmic Goiter.—Of 190 cases of exophthalmic goiter in which the patients underwent subtotal thyroidectomy during the years 1923 to 1928 at the Massachusetts General Hospital and which were followed for from three months to nearly six years after operation with frequent physical examinations and tests of basal metabolism, Thompson et al. found that 37, or 19.5 per cent, showed definite clinical evidence of postoperative thyrotoxicosis with basal metabolic rates ranging from plus 19 to plus 63 per cent without medication. In only two instances was there evidence that it was a true recurrence rather than a persistence of the disease. In three cases, however, regeneration of thyroid tissue was observed in association with a persistence. The postoperative thyrotoxicosis lasted from about two to four years in the three cases in which it finally disappeared without further surgical measures or roentgen treatment. It lasted for at least one year in nineteen others and at least from four to six years in four others. The degree of thyrotoxicosis was usually not severe, with a single exception it was less than before operation. In eighteen cases the basal metabolism could be held at a constant level for from months to years by the prolonged administration of iodine. In ten cases in which iodine was ineffective or eventually became so or in which it did not abolish the thyrotoxicosis completely enough reoperation was recommended. In seven cases roentgen therapy was tried with fair results in five instances. From a preoperative standpoint there was no definite distinguishing mark between those patients who had thyrotoxicosis following

operation and those who did not. There was a rough parallelism between the amount of thyroid tissue palpable after operation and the degree of thyrotoxicosis. The surgeons who did the most radical thyroidectomies (synonymous in general with those who had the most experience) had definitely a smaller percentage of cases of postoperative thyrotoxicosis than did the surgeons who had less experience and who usually did less extensive thyroidectomies. In the cases of persistence of the disease, the authors did not note any relapse except those caused by the omission of iodine or any remissions except those caused by its administration and the disappearance of the disease.

Neutral Red Test in Pernicious Anemia.—During the past year Cohen et al. were able to demonstrate the presence of injected neutral red in the gastric extractions of three patients who had pernicious anemia. They were unable to state whether the neutral red recovered in the gastric extractions of these patients was actually secreted by the gastric glands or whether it was regurgitated from the duodenum into the stomach. The possibility that the neutral red recovered in these cases was of gastric origin cannot be excluded. A simple and rapid method for the detection of neutral red in the gastric content is described.

Diagnostic Value of Sugar Tolerance Curve in Endocrinopathies.—As the result of the analysis of 500 sugar tolerance curves plotted by the same technician, and being the same method, Glassberg feels that the sugar tolerance curve as it has been used is a routine up to this time does not yield information of any diagnostic value in the differentiation of normal and endocrinopathic conditions. Analysis of curves reported within a few days of the first routine sugar tolerance test shows no uniformity in the results, thus precluding further a diagnostic interpretation of the curve obtained. Careful determination of the capillary (arterial) and venous blood sugar after the administration of a standard dextrose meal with and without the ingestion of water shows no uniform deviation in the form of the curve. Such an analysis did show that the intake of fluid alone produced a tremendous but not a constant deviation in the curve.

Reflex Influence of Colon, Appendix and Gallbladder on Stomach.—A reflex stimulation of the stomach from the colon, appendix and gallbladder was demonstrated by Smith and Miller. This effect which was indicated by an increase in the tone, particularly of the pyloric portion, and by an increase in the depth of the peristaltic waves, was completely abolished by atropine. In this study, however, all operative procedures incident to the experiment were completed prior to the registration of the control curve and thus the possibility of an irritation from the peritoneum producing the results was eliminated. These observations on patients are in line with the experimental studies on the dog and constitute a further demonstration of the reflex connection between the colon and the stomach.

Origin of Urobilinogen.—Rabinowitch records a clinical experiment which appears to demonstrate that urobilinogen may be found in the body not only outside the intestinal tract but also in the absence of bacteria as reducing agents.

Sphenopalatine Phenomena.—The Byrds bring together the more important observations that have accumulated in the literature on the sphenopalatine ganglion during the past twenty-five years and the more important observations that have been made during eight years of original work on this subject. The original work includes more than 2,000 cases and more than 10,000 instances counting multiples and repetitions, of remote dysfunctions. Dysfunctions numbering more than three score have been relieved by anesthetization of the sphenopalatine ganglions, including afflictions as intractable as progressive deafness as painful as migraine and iritis and as grave as glaucoma and angina pectoris. Anesthetization of the sphenopalatine ganglion does not give relief in all cases or any one malady but may be confidently expected to do so in at least one fifth of all cases of the several serious afflictions mentioned, which is equal to relief in all cases of one of them. Besides this, anesthetization of the sphenopalatine ganglion gives relief in a certain percentage of cases of more than three score other dysfunctions ranging from sciatica and pruritus to chorea and hypertension. Furthermore while anesthetization of the sphenopalatine ganglion has not in itself accomplished the conquest of

any one disease it has led directly to the therapeutic mystery of hay fever, vasomotor rhinitis and polypoid degeneration. The authors believe that anesthetization of the sphenoplatine ganglion should be a routine procedure in every one of the dysfunctions enumerated, not only as a preliminary test but also a therapeutic measure in cases that show a positive reaction.

Serum Treatment for Chronic Ulcerative Colitis—Bargen et al. assert that the fasting antibody solution obtained by precipitation in ether-water of the specific immune serum of chronic ulcerative colitis adds a new and valuable reagent to the armamentarium used in the treatment for bacterial chronic ulcerative colitis. It is particularly efficacious in the treatment of the more severe, subacute cases in which ileostomy was formerly the treatment of choice. This in conjunction with the specific vaccine and other symptomatic agents, has greatly reduced the need of ileostomy. Operation, and primarily ileostomy, had become limited to complications, with very few exceptions. Fifty consecutive unselected cases received the antibody solution. All the patients are living more than a year after treatment. Twenty-four patients became free from symptoms; thirteen became from 75 to 90 per cent well, and six were improved at least 50 per cent. In only seven cases was there little if any change following the treatment. These seven cases were either severe, long-standing cases with extensive involvement of the colon and destruction, or there were serious complications, such as multiple polyps or strictures.

Pericardiectomy in Treatment of Pick Syndrome—A method for the production of this disorder experimentally is described by Beck and Griswold. It consists of the application of surgical solution of chlorinated soda in the pericardial cavity. The introduction of this solution results in generalized intra-pericardial adhesions, thickening and fibrosis of the parietal pericardium and sometimes of the epicardium, with fluid in the chest enlargement of the liver together with a fibrinous exudate on the liver, and sometimes pulmonary and subcutaneous edema. Observations on the experimental production of the Pick syndrome and its relief by pericardiectomy are presented. Observations on a clinical case of the Pick syndrome and its relief by pericardiectomy are given. A new exposure for the resection of the pericardium is presented.

Anterolateral Costectomy for Inadequate Collapse Following Posterior Extrapleural Thoracoplasty—During the last four years Hedblom has performed this secondary

anterolateral costectomy in twenty-six cases. The indications were persistent symptoms after the posterior thoracoplasty in eight cases, and recurrence of symptoms after a symptom-free period of four months in one and of ten months in another. There was an average grade of collapse of the thoracic wall from the posterior resection in all these cases. In three, regeneration of the ribs in the course of a multiple stage operation prevented a satisfactory anatomic degree of collapse, and symptoms persisted in all. In two there were large unobliterated pulmonary cavities and persistent pneumothorax cavities. In eleven there were unobliterated empyema cavities secondary to active pulmonary tuberculosis. The parietal pleura overlying a residual cavity was resected later in all of these cases, with complete healing. In all these cases the anterolateral resection was tolerated as well as or better than the posterior resection. There was one death attributable to the operation from sepsis and one death from hemorrhage.

Unfavorable Results of Phrenicectomy—Berry points out that there is a definite risk associated with crushing, resection or avulsion of the phrenic nerve. Fifty-seven cases have been reviewed in which phrenicectomy was most detrimental; twenty-six of the patients died as a result of the operation. These poor results have all been subsequent to properly performed operations without technical error. In view of the fact that there is such widespread advocacy of phrenicectomy as a harmless procedure in cases of pulmonary tuberculosis, bronchiectasis and even abscess of the lungs, Berry deems it wise to sound a word of caution and to call attention to the risk involved, slight though it is.

Treatment for Penetrating Wounds of Pleural Cavity

—Of the 162 cases reported by Allen 47 were stab wounds and 115 gunshot wounds of the chest. Seven of the cases of stab wound proved fatal, but the cause of death was associated stab wounds of the abdomen in five cases and immediate hemorrhage from the heart in two cases. No patient died of injury to the lung. Hemothorax occurred in forty-two of the forty-seven cases. Two patients were operated on for ligation of the intercostal artery. The pleural cavity was not explored in either of these cases. In the 115 cases of gunshot wounds of the chest, only five patients died when the pleural cavity only was entered by the bullet. Two of these died immediately of hemorrhage, and three died later as a result of infection of the pleural cavity and injured lung. A total of 27 of the 115 patients died. Twenty-two of these cases were complicated by associated wounds of the abdomen, spinal cord and skull. It is evident that patients with ordinary bullet wounds of the chest usually survive unless there are associated wounds that cause death. One of these patients died from associated injury of the left ventricle. This was correctly diagnosed and the mediastinum was immediately explored. The apex of the heart was found to have been shattered by the bullet to such an extent that it was impossible to check the hemorrhage. Bullets were removed from twenty-one of the 115 patients with gunshot wounds. In fifteen cases the bullets were embedded in the wall of the chest and could be removed without disturbance of the lung. In six cases the bullets were removed from the lung but in no instance before two weeks had elapsed after the injury.

Etiology of Primary Bronchiectasis—Smith states that the essential lesion in primary bronchiectasis is a local necrosis of the elastic tissue in the bronchial wall due to infection with the fusospirochetal group of anaerobic organisms. This fusospirochetal group comprising *Treponema macrodentium*, *Treponema microdentium*, *Spirochaeta vincenti*, *Spirochaeta buccalis*, fusiform bacilli, vibrios and cocci are the same organisms that are found in pyorrhea alveolaris, Vincent's angina, pulmonary abscess and pulmonary gangrene. These organisms have been seen in the sputum of forty-nine of sixty patients proved to have bronchiectasis by the iodized oil test. Spirochetes and fusiform bacilli were found in sections of bronchial dilatations after staining by Levaditi's method in eight or twelve cases that came to necropsy. Fusiform bacilli were demonstrated in pathologic sections from four of an additional six cases of bronchiectasis after staining by Goodpasture's method. In animal experiments, fusospirochetal material from varied sources (pyorrhea alveolaris, fusospirochetal bronchitis and pulmonary abscess) caused bronchiectasis as well as pulmonary abscess and pulmonary

gangrene in rabbits. Control inoculations with pure cultures of (1) *Staphylococcus aureus*, (2) aerobic hemolytic streptococci, (3) anaerobic hemolytic streptococci, (4) green producing streptococci, (5) anaerobic streptothrix, (6) Friedländer's bacilli and (7) influenza bacilli failed to produce damage to the bronchi. The fusospirochetal group of organisms is probably the cause of primary bronchiectasis.

Air in Peritoneal Cavity—The position and mobility of the diaphragm were studied by Overholt in animals under sodium amylethyl barbituric acid anesthesia. It was observed that following the introduction of air into the peritoneal cavity, either by injection or as a result of laparotomy, the diaphragm assumed a higher position and its excursions were definitely restricted.

Esophagus, Stomach and Heart Following Unilateral Phrenicectomy—Twenty seven patients were examined by Brillou et al. before and after phrenicectomy performed for pulmonary disease. Five patients complained of the following symptoms after phrenicectomy: one of eructations of gas, another of heart burn, a third of vomiting and two of dysphagia. In all but one instance these complaints were temporary. With but one exception they followed left sided phrenicectomy. A case of cardiospasm that apparently followed phrenicectomy is recorded. No marked mechanical displacement or shift of the upper third of the intrathoracic portion of the esophagus was noted after phrenicectomy. Slight respiratory deflection of the lowermost intrathoracic portion of the esophagus was noted. The electrocardiogram showed no marked changes following phrenicectomy. Four patients showed changes in the height of the complexes but not in their shape. Two followed left sided and two followed right sided phrenicectomy.

Dextrose by Rectum—Evidence of Nonabsorbability

—The administration of dextrose by rectum is a common therapeutic procedure, especially as a part of postoperative treatment and when oral feeding is difficult or impossible. The dextrose is usually given by the drip method or, at a faster rate, in the form of nutrient enemata. An isotonic solution of the sugar is usually given by drip, but with the dextrose enema the concentration of the sugar is often much higher. Little thought has been given to the effectiveness of such therapy, whatever has been the technique used or strength of dextrose solution injected. Smith asserts that the evidence that even a small part of the injected dextrose is absorbed is still inconclusive, whether an isotonic or hypertonic solution is used, since the reported increases in blood sugar and respiratory quotient are too slight to be definite proof of additional dextrose intake. Experimental data show that the blood sugar can be decreased by the instillation of dextrose in any strength of solution into the lower bowel. It is possible to bring about a degree of hyperglycemia in this way in the more sensitive patient that would be sufficient to lower both blood pressure and blood volume or disturb the acid-base balance similar to that seen in overdosage of insulin in diabetes with a sharp shift to an alkalosis. Such circulatory disturbance, without an associated chemical imbalance may complicate and prolong postoperative convalescence.

Obstruction Following Gastro-Enterostomy—Fairchild presents a brief review of the steps in the evolution of gastro-enterostomy with the observation that postoperative obstruction has not been uniformly eliminated by any procedure. He asks whether the failure always to avoid postoperative mechanical

obstruction may not be due to the application of a too nearly standardized technique to all individuals without giving consideration to their great variations in anatomic structure. He stresses the fact that, before operation, the relative positions of the structures concerned in a gastro-enterostomy are not fixed. After operation they are fixed and, unless the mechanics of the situation are so worked out that they will be fixed in a relatively normal position without stress or angulation, dysfunction will result. Suggestions are made as to the modifications necessary in the length of the afferent loop, the position of the opening in the transverse mesocolon and the position and character of the stoma made necessary by the anatomic variations of individual to secure a relatively normal relation of the structures after operation.

Treatment of Barbitol Poisoning with Dextrose—Sanderson reports a case in which the administration of dextrose intravenously saved the patient's life. A man took forty tablets (200 grains or 13 Gm.) of barbitol with suicidal intent, at 3 p. m., September 1. He was deeply comatose and unable to swallow, his face was flushed, there was deep, stertorous breathing and he could not be roused by any means. Reflexes were present, but there was almost no voluntary muscular movement. At 7:30 p. m. his stomach was washed out, and epsom salt was instilled. Strong coffee was given both rectally and by mouth several times as well as other stimulants but without effect. Large involuntary bowel movements and involuntary urination occurred several times. Despite treatment, the patient became progressively worse. At 8 p. m., September 2 he was cyanotic, the pupils were dilated, the temperature was 102.6, the pulse was 150, and respirations numbered 64. He appeared about to die. Light hundred cubic centimeters of 20 per cent dextrose was given intravenously. An hour later the patient had a chill and became restless, moving about for the first time since entry. This condition continued throughout the night. At 6 a. m. the patient began talking incoherently and for the first time could swallow. The following day, September 4 he was semiconscious but confused. September 5 he was improved, and September 6 was quite rational.

Sodium Amytal for Alleviation of Pain During Labor—Swendson asserts that when the dosage and intervals are individualized, the intravenous administration of sodium amytal during the latter half of the first stage and during the second stage of normal labor induces satisfactory amnesia in nine out of ten cases. Labor is rarely, if ever prolonged by its use and may sometimes be hastened. There is no evidence of harm to the mothers. Slight to extreme restlessness results from its administration in half of the patients and is an objectionable feature of the procedure. Restlessness can be controlled toward the end of the second stage and delivery facilitated by the use of an inhalation anesthetic of which lesser amounts than usual need be administered. One third of the babies are somewhat apneic at birth apparently because of a torpidity of the respiratory center induced by the drug and require stimulation to establish respiration. No other deleterious effects of the drug are observed in the postnatal behavior or weight changes of the babies.

Sodium Amytal in Nervous Disorders—Gowin has used this drug in the various types of cases that one encounters in the usual psychiatric practice. He has used it to a large extent, for its sleep-producing action. He found it a most excellent drug in controlling convulsions when given intravenously. He has also used it in four cases of idiopathic epilepsy. These cases have been observed over a period of from three to four months. The average dose has been from $1\frac{1}{2}$ to 3 grains (0.1 to 0.2 Gm) two or three times a day. These patients were all previously given phenobarbital. In two cases there was no perceptible change in the frequency or severity of the convulsions. In one case the convulsions were more severe and more frequent than when phenobarbital was given and in one case the patient reported longer intervals between convulsions and some improvement in his general feeling of well being. However these cases have not been observed over a sufficient length of time to draw definite conclusions as to its value in epilepsy. As a daytime sedative in psychoneurotic cases it has been Gowin's observation that the drug unless given in very small doses has too great a soporific action and if given in small doses its action is very transient. As a soporific in psychoneurotic cases and also in psychotic cases attended by marked excitement and depression with severe insomnia when given in carefully adjusted doses, it is a real aid in obtaining sufficient restful sleep with a minimal degree of depressant action.

Iodine Content of Blood of Patients Suffering from Cancer—The results of Fowweather's investigation show that there is no uniform reduction of the blood iodine in cases of cancer. Out of twenty four cases examined only eleven show values below what may be considered as normal. This failure to find a constant association between low blood iodine and cancer is said to be definite evidence against the view that iodine deficiency is a cause of cancer. While there may perhaps be a tendency toward lowered blood iodine in cancer there is at least as much justification for assuming that the reduction is the result of the cancerous condition as there is for assuming it to be the cause of such a condition. Further since in rather less than half of the cases examined there was reduction of blood iodine indicated the determination of blood iodine as a diagnostic test for the presence of malignant disease can have no value whatever.

Two Types of Bilirubin Diazo-Reaction in Serum—An attempt has been made by Hunter to determine the probable nature of the two kinds of diazo reaction for bilirubin obtainable in icteric serums. The so called direct reaction is said to be most probably due to the presence of sodium hydrogen bilirubinate and the so-called delayed reaction to the presence of free bilirubin in an undetermined solvent that is soluble in alcohol.

Influence of Intravenous Injection of Urea—The results of the intravenous injection of 5 Gm of urea in health and in various diseases were investigated by Donovan and Brenner. At the time the urea has mixed with the blood (three minutes) 80 per cent has left the blood stream. It is suggested that the urea leaves the blood by a process of simple diffusion passing into the water of the cells as well as into the free water and that the process is complete in fifteen minutes when the concentration of urea in the blood equals that in the tissues. A review of the literature indicates that urea is unique in this respect. With no other substance investigated is the distribution uniform over blood and tissues and in most the concentration in some tissues is greater than in the blood showing that the

process by which the substance enters the tissues is not one of simple diffusion alone. It is suggested that the sudden introduction of urea into the body delays the formation of urea and may even bring it to a standstill for the first two hours after the injection. The importance of this in connection with the production of uremia is mentioned. Evidence is discussed in favor of the view that except in edematous patients urea injection causes some salt to pass out of the body fluids to be stored in a dry form in the salt depots of the body, thus reducing the crystalloid concentration of the body fluids which had been raised by the injection of urea, but that in most cases of edema salt is liberated from the depots and enters the body fluids. It is pointed out that the capillaries are completely permeable to water and to most of the substances dissolved in the blood plasma and are partly permeable to the plasma proteins. The factors retaining the blood inside the vessels are discussed. None of the causes ordinarily mentioned seem sufficient. It seems probable that the true cause must be sought in the tissues rather than in the blood or blood vessels. It is suggested that perhaps the amount of fluid leaving the blood is limited by the capacity of the tissues for taking up water and that this in its turn may be influenced by changes in the acid base balance or by alterations in the relative proportions of various ions. A review of the literature shows that in experimental edema usually less fluid passes into the tissues after intravenous injection, than in nonedematous animals, suggesting that an important factor in the production of edema is a deficient power of the tissues to hold and bind water which therefore accumulates in the tissue spaces as edema fluid. The authors' results suggest that in edema the tissues are also less able to bind salt, which accumulates also in the free tissue fluids.

Response of Grain-Fed Pigeons to Substances Effective in Pernicious Anemia.—Experiments dealing with the administration of substances effective in pernicious anemia and other test material to grain fed pigeons are described by Vaughan et al. The oral or intravenous administration of liver preparations effective in anemia produced a consistent pronounced response of the reticulocytes, and one preparation and two subfractions prepared from it which had received no clinical tests also caused a similar response. Beef steak was as effective as potent liver preparations in causing a rise of the reticulocytes. No reticulocyte response was obtained to (1) a liver preparation which was inert for pernicious anemia, (2) a liver extract in which the active principle had been destroyed, (3) vitamin B₁ and B (4) histamine, (5) sodium chloride and (6) casein. An isolated observation suggests that sepsis interferes with the action of a potent liver preparation in pigeons as it does in pernicious anemia. Substances capable of influencing the reticulocyte level are without effect on the total red blood cell count. The grain fed pigeon may perhaps suffer from a mild dietary deficiency, which is possibly a factor of importance in permitting its bone marrow to respond to certain substances.

Method of Exciting Incipient Movement in Paralyzed Muscles.—The methods described here by Porritt and Smith aim at eliminating all checks to the activity of the weakened muscles by counterbalancing the weight of the limb inducing a relaxation of the opponent muscles, and finally counteracting almost entirely inertia, friction and gravity. This allows the feeble minimal efforts of the affected muscles to act not in the stationary limb but in association with pendulum movements, maintained by the operator at first and later by the patient. The apparatus necessary for this purpose is an overhead bar with ball-bearing pulleys through which run adjustable ropes and slings. By this means the faintest return of power is allowed free play, the activity of the muscle contributes to its

more rapid recovery and the patient, persuaded by the wide range of movement into thinking that he is accomplishing more than is actually the case, is encouraged to exert every effort without the usual fear of pain, thereby hastening restoration to normal function.

Uterine Hemorrhage Malignant Disease.—One form of uterine bleeding, emphasized by Whitehouse as being a most important perhaps the most important, diagnostic sign is cancer of the uterus, namely the hemorrhage that occurs as a direct result of coitus. Continued hemorrhage must always be regarded with the greatest suspicion. It is true that a blood stained discharge or in some cases slight actual hemorrhage some times follows coitus, when the cervix is the seat of an extensive erosion and ectropion or when a simple polypus is projecting through the os externum. A severe bleeding associated with coitus is however nearly always evidence that cervical carcinoma exists and a careful examination of the cervical tissues is demanded. In 1929 4,428 women died in England and Wales from malignant disease of the uterus, a mortality rate of 215 per million females.

Mutation and Pathogenicity Experiments with BCG.—The pathogenic properties of two strains of BCG have been investigated by Dreyer and Vollum. Deep bouillon subcultures of BCG (1) produced generalized tuberculosis in all of twenty-eight guinea pigs inoculated intraperitoneally with doses of from 0.1 to 20 mg, and produced severe progressive tuberculous lesions in all of twelve rabbits inoculated intravenously with doses of from 5 to 50 mg. Twenty-two of twenty-three guinea pigs infected either directly with tuberculous material from these animals or with cultures from the tuberculous material developed generalized tuberculosis. *Bacillus tuberculosis* was found in cultures from the heart blood of all of the twenty-eight guinea pigs injected directly with deep cultures of BCG (1), and in nineteen of the twenty-three guinea pigs infected with pathologic material or cultures obtained from the animals originally infected with culture. The pathogenicity of BCG 359 was tested on guinea pigs. One of twenty guinea pigs injected with the culture is recovered from the Pasteur Institute died from an unknown cause 672 days after an intraperitoneal dose of 5 mg having caseous tuberculous lesions without signs of healing in the right testis and the left epididymis. Deep bouillon subcultures of this strain were tested on fifty-six guinea-pigs, twelve of them receiving doses of 10 mg intraperitoneally, of these twelve three that were killed and two that died had definite progressive tuberculous lesions and four of the five had caseous abscesses in the testes or epididymides.

Electrocardiographic Changes During Brief Attacks of Angina Pectoris.—In five cases Parkinson and Bedford were able to obtain electrocardiograms during and after short paroxysms of anginal pain. These showed that the ventricular deflections were modified during the paroxysm of pain and that the modifications disappeared with the pain. In none of these cases was there any question of coronary thrombosis at the time the records were taken though one patient had probably had coronary thrombosis three months previously. In all these five patients electrocardiograms taken during short anginal paroxysms showed definite and transitory changes in the ventricular deflections. There was a depression of R T and a diminution in the amplitude or inversion of the T waves in one or more leads changes closely resembling though not so pronounced as those which follow cardiac infarction in the early stages. It is significant that both transient anginal pain and cardiac infarction can affect the electrocardiogram in a similar manner and it seems reasonable to infer that the mechanism underlying this electrocardiographic change is essen-

tally the same in the two cases—in ischemia of a part of the cardiac muscle

Liver Preparations in Diabetes—Brett et al have carried out Blotner and Murphy's directions for the preparation of their special extract of liver on several occasions and have consistently found that the extract was quite ineffective in lowering the blood sugar of normal rabbits when administered in suspension by stomach tube in doses equivalent to one tenth pound of liver, a quantity which, according to Blotner and Murphy, is equivalent to about 1 unit of insulin. In the authors' experience an injection of 1 unit of insulin produces a considerable fall in blood sugar in the type of rabbits usually employed for insulin assay. Extracts were prepared from both fresh and frozen liver by the Blotner and Murphy process and extraction periods of both twelve and forty eight hours were tried but in no case was any hypoglycemic effect observed. Liver extract (Boots) prepared by the Medical Research Council's process was also found to have no hypoglycemic action. In fact in practically all cases a slight but definite hyperglycemia resulted.

Estimation of Protein in Urine—In the method described by Kerridge, the urine is mixed with a carbon suspension and carbon and protein are simultaneously precipitated with trichloroacetic acid. The grayness of the precipitate depends on the amount of protein, when the amount of carbon is constant. The tone is compared with standards.

Vaccination of Nuislings with BCG in Foreign Countries: Effects on General Infant Mortality—The results of an extensive investigation of the effects of vaccination of nuislings with BCG were reported at the Seventh Conference of the International Union Against Tuberculosis held in Oslo in August 1930. Calmette says that the absolute innocuousness of the vaccine was again confirmed by bacteriologists from many nations. No basis was found for the recent claims that certain strains of BCG, namely type S (smooth), could be isolated which would produce progressive tuberculous lesions; the investigators were unable to isolate such strains themselves and their examination of cultures furnished them of type R (rough) and type S showed that both had been contaminated by other virulent bacteria. Reports from all the countries of Europe except Austria, Great Britain and Portugal and from Argentina, Brazil, Canada, Chile, the Belgian Congo, Cuba, the United States of America, Japan, Maurice Island and Uruguay showed that systematic vaccination of nuislings with BCG had produced a marked decrease in the general mortality from all causes among nuislings. It was noted moreover that the mortality during the first month of life before the effects of the vaccination have time to be manifested remains approximately the same among vaccinated and nonvaccinated infants. This seems an additional reason for attributing the decreased number of deaths during the first year to the effects of vaccination with BCG. The general mortality was diminished by about 20 per cent by the vaccination while deaths from tuberculous infection were practically eliminated. Since the deaths

from tuberculosis have never been more than a very small proportion of the total number, it is logical to assume that vaccination with BCG increases the infant's resistance not only to tuberculosis but to other infections as well.

Vaccination of Human Beings Against Undulant Fever—Human beings develop undulant fever through either accidental or professional contact with sheep, goats or cattle with melitococcosis. Because of the great extent of the disease among animals and the impossibility of avoiding contact with infected animals or of knowing which ones are infected, the only satisfactory prophylaxis for all persons living in a region where melitococcosis has developed and having any contact with animals is preventive vaccination. Dubois and Sollier report that among 111 persons vaccinated, all of whom were directly exposed to infection there were no cases of undulant fever. On the other hand among thirty six persons who were not vaccinated, about 75 per cent of whom had no direct contact with infected animals, two cases of fever developed. Since the vaccinations took place within from three to eight months previous to the time of writing the authors have no data as to the duration of the immunity produced. They describe in detail the preparation of the vaccine used which is a combination of strains of *Brucella melitensis* and *Brucella abortus* from both animals and human beings. They also give definite instructions for the administration of the vaccine. No harmful results have been produced by the vaccination.

*Combination of Splenic and Renal Rupture R. Desjacques, T. Barard and H. Lathuraz Viollet—p 296

Combination of Splenic and Renal Rupture—Although the combination of splenic and renal rupture is not found frequently Desjacques et al feel that it is of sufficiently frequent occurrence to deserve a careful study. The lesions observed in the spleen are always serious while the associated renal lesions may or may not be important. The authors attribute this to the fact that minor lesions of the spleen do not produce definite symptoms and are usually never detected. The ruptures are usually caused by a severe traumatism. Shock symptoms are almost always observed immediately afterward followed by signs of internal hemorrhage and by more or less violent spontaneous pain in the region of the left flank. Although the entire abdomen may be painful a more distinct pain produced by palpation in the left flank is a significant symptom. Contraction of the abdominal wall near the spleen is often present; the authors consider it probably the most specific of all the symptoms. If the kidney is involved in the lesions hematuria and a lumbar hematoma are usually present. The evolution in such cases is always fatal unless intervention is practiced immediately; death occurs in from two hours to three days. Surgical treatment is the only possible remedy; the medical treatments used being merely palliative and supplementary. Since local anesthesia does not permit a thorough examination of the abdominal cavity and spinal anesthesia is dangerous for patients in a weakened condition the use of general anesthesia is recommended. Since the symptoms often do not justify a precise diagnosis an exploratory laparotomy should be made with a median or supraumbilical or a subumbilical incision depending on the case. The authors describe several operations for the treatment of lesions in different localizations. They particularly emphasize the necessity for early recognition of the symptoms and prompt intervention.

Revue de Medecine, Paris

17 710 1 (Nov) 1930

- Tetiform Solar Crises in Course of Gastric and Duodenal Ulcers C. J. Udaondo, M. M. Calmette and C. I. Goulet—p 19
Diarrheas of Hepatic Origin C. F. J. Desjardins and H. Deleury—p 4
Ga Tro Enterolesy in 1929 J. Kachet—p 6

Tetiform Gastric Crises in Course of Gastroduodenal Ulcers—Udaondo et al show that in the course of gastric and duodenal ulcer painful attacks often occur that resemble the gastric symptoms of tabe. In fact the resemblance is so marked that it often leads to an incorrect dia-

nosis of tabetic conditions. However, it is always possible to eliminate tribes by a clinical examination that reveals the absence of the neuropathic and humoral characteristics of this disease. Moreover, analysis of the gastric and duodenal secretions, the existence of latent hemorrhages, when they are present and roentgen examination make an accurate diagnosis possible. Various theories as to the pathogenesis of the tabetic-form crises have been proposed. The two explanations considered most sound by the authors are that neuritic lesions induce solar neuritis and that pancreatic sclerosis by a mechanical action produce the same symptoms. The authors recommend, in general the use of the same medical treatment as in ordinary ulcerous conditions, for instance the administration of anti-spasmodics such as papaverine, atropine and belladonna. However, if medical treatment does not bring relief and certainly if one suspects the existence of a pancreatitis that seems likely to develop further surgical intervention is indicated. The authors do not venture to prescribe the operation of choice; they suggest that in this condition the case should be turned over to a good surgeon who should be able to solve the problem on the basis of the previously obtained diagnostic and clinical data.

*Local Tuberculinic Allergy in Pulmonary Tuberculosis C. Borsellino—p. 1134

Latent Acidity of Urine in Hepatic Cirrhosis G. Donini—p. 1147

Local Tuberculinic Allergy in Pulmonary Tuberculosis—Borsellino applied to about 100 patients with pulmonary tuberculosis skin tests with tuberculin at various points of the two hemithoraces, starting with the conception that the skin reaction to tuberculin is not the expression of a humoral action but the result of the skin changed in its trophism due to tuberculous toxins. The results as shown in figures and roentgenograms reveal positive skin reactions to tuberculin in one hemithorax and negative reactions in the other hemithorax. Furthermore, in one and the same hemithorax positive reactions were obtained in various points and negative reactions at other points. In correspondence with the diseased organ the positive reactions indicated lesions of a productive nature and the negative reactions lesions of an evolutive nature. Hence, the system of skin tests with tuberculin would localize the various areas of the lungs where tuberculous foci exist, thus furnishing a criterion of the state of evolution.

*Insulin Therapy in Emaciation Following Calculous Cholecystitis D. Ceccarelli—p. 1665

Tumors of Kidney P. Emiliotti—p. 1672

Insulin Therapy in Emaciation Following Calculous Cholecystitis—Ceccarelli, after a short survey on insulin treatment in emaciation states in general, reports a case of marked emaciation (loss of weight 20 Kg) following cholelithiasis, in which insulin (20 units per day in two doses) was administered. The surprising outcome (gain in weight of 17.8 Kg), with a return of general conditions almost to normal, induces the author to advise insulin treatment in such emaciation states.

*Achondroplasia in Two Brothers F. de la Torre and G. Allende—p. 440

Achondroplasia in Two Brothers—De la Torre and Allende report two cases of marled achondroplasia in brothers, aged 20 and 6 months, respectively. The children (sons of first cousins) were mentally and physically normal except for the achondroplasia. The oldest child had the typical symptomatology of the abnormality. The youngest besides the marked achondroplasia had a dorsolumbar kyphosis which at the roentgen examination appeared like a kyphosis caused by rickets. Both children presented marked dwarfism for their ages. Neither the parents nor the children had syphilis. The parents were of a height above normal. The father was almost a giant.

He had however slightly noticeable achondroplastic hand. The authors consider the father as an atypical achondroplastic person. Several theories on the pathogenesis of achondroplasia are reviewed. The authors state that, in their case, congenitality was responsible for the condition of the children. They based their statement on the following fact: The father had three normal children from his first wife. This fact, the authors believe, points out that his union to a person to whom he was not related caused the disappearance of a possible familial predisposition for the inheritance of a condition which the father exhibited in an atypical form. On the contrary, the union with his second wife (his blood relation) accentuated that propensity, according to the laws of atavism which probably existed in both him and his wife as a familial stigma, resulting in the complete development of a typical form of the condition.

Colitoxin Composition—Plantenga describes experiments on guinea pigs in which he demonstrated that the substance that he had previously proved to be the etiologic factor for the syndrome of alimentary intoxication and had designated as colitoxin is a compound one. It is composed in part of a substance bound to the colon bacillus and in part of a substance eliminated by the colon bacillus during its growth apparently in aggression. Both the coli endotoxin and the coli aggrassin are, when acting alone, nontoxic. The coli aggrassin, however, inhibits the phagocytic action of the leukocytes so that the dead colon bacilli and the endotoxin bound to them cannot be rendered harmless and the endotoxin exerts its toxic action. As a result syndromes appear that are essentially of purely bacterial origin and result in the clinical picture of intestinal catarrh. This condition is not an 'alimentary intoxication' (Finkelstein) but a colitoxicosis.

Effect of Ingestion of Vitamins on Chemical Composition of Mother's Milk—Greiner and Mosonyi studied the effect of an increased ingestion of vitamins A and B by nursing mothers on the chemical composition of their milk, at the same time note was taken of the increase in weight of the nurslings and their reaction to intercurrent diseases. As a result of the increased ingestion of vitamins the fat content of the milk increased in 41.2 per cent of the women remained normal in 31.6 per cent and dropped below normal in 31.6 per cent. In 33 per cent of the cases a slight increase in the ash content of the milk was demonstrated. The amounts of the other constituents of the milk remained normal. The nurslings of the women to whom the vitamins had been administered showed a 15 per cent greater increase in weight and a greater resistance to intercurrent diseases than did the nurslings of the women to whom the vitamins had not been administered.

Genesis of Diaphyseal Foci in Bones of Nurslings with Congenital Syphilis—Schonfeld reports a case of multiple foci of degeneration in the diaphysis of the long bones of an infant with congenital syphilis. Because of band shaped shadows of great density and approximately parallel to the epiphyseal lines he believes that the foci of degeneration in the diaphysis of the bones were not the result of primary osteitic or osteomyelitic syphilitic processes but of osteochondritis.

Whooping Cough Vaccine Treatment—According to Leitner vaccine treatment represents a great advance in the crusade against whooping cough. It should be begun early on the basis of a diagnosis made by means of a leukocyte count. The injections should be given subcutaneously or intramuscularly at intervals of from twenty-four to forty-eight hours.

Large doses of a concentrated vaccine give the best results. If the desired action is not obtained the injections should be continued until from six to eight have been given. In advanced cases of whooping cough the duration of the disease cannot be shortened by means of vaccine treatment but the paroxysms can be rendered less severe.

Takata-Ara Reaction of Cerebrospinal Fluid in Meningitis.—On the basis of a study of the reaction in thirty cases of tuberculous meningitis and twenty cases of suppurative meningitis, Kasahara and Komishi state that the Takata-Ara reaction in the cerebrospinal fluid is not specific for meningitis. In tuberculous and suppurative meningitis the cerebrospinal fluid shows not only the rose-red Takata-Ara reaction but also other color reactions and the flocculation reaction. The fact that the pathologic cerebrospinal fluid shows a color reaction or a flocculation reaction depends on changes in the albumin globulin ratio. The Takata-Ara reaction of the cerebrospinal fluid is modified by previous ingestion of salts of bromine and iodine.

Thyroidectomy in Malacia of Trachea.—According to Sgalitzer, malacia of the cartilaginous framework of the trachea is one of the most dangerous complications of goiter. As a result of prolonged pressure atrophy parts of the cartilaginous framework may disappear completely. The trachea may then collapse under the pressure of the constricting goiter and produce severe asphyxia or even death. The condition occurs not only in old persons who have had a goiter for many years but also in young persons. The tracheal cartilages of youths up to the eighteenth year seem even more susceptible to pressure atrophy than do the tracheal cartilages of adults and may undergo a marked loss of resistance after only a few years. In twenty-six persons with benign goiter seven cases of severe malacia of the wall of the trachea were noted together with nineteen cases of definitely decreased resistance of the cartilaginous framework of the trachea. In all of the seven cases of severe malacia of the trachea, surgical removal of the goiter gave excellent end-results. The changes in the position of the trachea and the severe stenosis that was usually present were corrected in a short time. The return to normal was complete after four months. After this time there remained in four cases only a slight depression in the wall of the trachea. In two cases the lumen of the trachea was of the normal width and in one case there was a large concentric sacculation of the lumen of the trachea in the region of the malacia. The restoration of the lumen of the trachea was favored by the cicatricial retraction of the soft parts of the operative wound. Although the malacia persisted all seven patients were completely relieved of symptoms.

Acute Articular Rheumatism. Disturbances in Peripheral Nervous System.—Granström and Harrisomenowa state that not only do changes in the peripheral nervous system occur in acute articular rheumatism and other joint diseases but also the same zones of increased and of decreased cutaneous sensibility, paresthesias, irradiation of the pain to neighboring regions and painfulness of the nerve trunks occur in parietal and osteomyelitis as well as in fractures of bone and that these changes appear and disappear with the disease of the joints and bones. In some cases there occur also changes in the tendon reflexes. Zones of decreased and of increased cutaneous sensibility in the region of diseased joints occur frequently in acute articular rheumatism and like Herd's zones indicate a reflex modification of the cutaneous sensibility. Frequently the hyperesthetic and hyperesthetic zones occur close together. The zones usually have the shape of an irregular armband surrounding the joint and never extend beyond a region innervated by one nerve. The

disturbances in the peripheral nervous system that occur in articular rheumatism are not caused by degenerative changes in the nerves or in their branches but represent reflex phenomena of irritation. A review of the few cases of neuritis and polyneuritis of so called rheumatic nature reported in the literature revealed that in almost all the cases the dependence of the neuritis on rheumatism had not been demonstrated conclusively. The great rarity of typical neuritis or polyneuritis in articular rheumatism shows that the rheumatic virus has scarcely any affinity for the peripheral nervous system. The authors believe, therefore, that there is no basis for designating the neuritis or polyneuritis that appears after exposure to cold as rheumatic, the condition should be termed a refrigeration neuritis or a neuritis caused by an unknown infection.

Clinical Experiences in Serology of Tuberculosis.

Horing reports experiences with the complement fixation reaction in patients with tuberculosis. He points out that specific antibodies do not circulate in the blood during all stages of tuberculosis and therefore their demonstration is possible in only a part of the cases. The reaction can be positive only in those cases in which there exists not only a local, or a cell allergy but also a humoral allergy. It is also probable that in existing allergy numerous types of antibodies may be present, and only a part of them will react to one antigen (extract). For this reason it is advisable that several antigens be used. In patients with active tuberculosis it was found that during the early stages of the disease the complement fixation reaction was frequently negative. In the further course of the disease it was often observed that the reaction became positive. In order to be completely informed about the allergic conditions the author performed besides the blood test also Pirquet's skin reaction. The two reactions gave different results in many cases. Especially during the early stage when the complement fixation reaction was negative, the Pirquet skin reaction was strongly positive. When the complement fixation test was repeated on the day following the Pirquet test about one half of the patients gave positive reactions in the sense of a provocation of the serum allergy. The author comes to the conclusion that in many cases the complement fixation reaction is a valuable diagnostic aid however the negative reaction is often deceiving. The reaction is of no especial value for the detection of tuberculosis in patients who have not been thoroughly examined.

Relation of Dyestuff Excretion to Secretion and Morphology of Diseased Stomach.

Because the gastric mucous membrane is capable of excreting dyestuffs following their intramuscular injection Henning and Jurgens tested the excretion of neutral red in 161 persons. Some of these persons were healthy and the others had gastric disturbance. Nearly all of them had first had a gastroscopic examination. The method of the neutral red test was as follows. In contradistinction to most experimenters who inject the dye intravenously the authors injected it intravenously. This had the effect that the excretion period was considerably shortened. After the fractional withdrawal of the gastric juice had been completed 5 cc of a 1 per cent sterilized solution of the dye was injected intravenously. By continuous withdrawal of the gastric contents by means of a retention catheter the first appearance of the dyestuff in the stomach was detected. It was found that in patients with atrophy of the gastric mucous membrane and in cases of gastritis with complete achylia there was no excretion of dyestuff through the stomach. In a few cases of erythritic gastritis the dyestuff appeared very late in the stomach. In the various forms of atrophic gastritis either normal or retarded excretion was noted. In subacidity in normal acidity and in hyperacidity the excretion showed no difference. In twenty-four healthy persons with normal acidity or with hyper-

acidity the same average excretion period was observed as in patients with the various organic disorders of the stomach. From this it may be concluded that the excretion of the dye in the stomach is independent of the secretion type, as long as the hydrochloric acid secretion is maintained. In three cases of histamine refractory functional achylia with normal mucous membrane normal excretion periods were observed. This seems to indicate that the excretory function of the gland cells cannot be inhibited by psychic influences.

Diagnosis of Latent Thrombosis—Von Hagen reports the case of a woman aged 35 who had undergone hysterectomy on account of uterine myomas. The postoperative course was normal. However on the fourth day the patient felt a severe pain in the right shoulder. This pain persisted for about four days. On the thirteenth day after the operation the patient showed for the first time an increased temperature and three hours later she died. The author thinks that the pain in the shoulder indicated a pulmonary embolism which was caused by a thrombosis in a pelvic vein. The pain which is a warning signal the patient should not have been allowed to be up but should have been kept in bed and treated with morphine. The author is aware that the concurrence of latent thrombosis and Herd's zone is not a daily occurrence. However, if, following an operation or in the course of a prolonged bed rest a Herd's zone appears it may be assumed that somewhere a thrombosis exists which has caused a silent embolism in the viscera corresponding to the area of cutaneous painfulness, and preventive measures should be taken.

Is Maniolo's Seroreaction for Pregnancy Practical?—Rodcutt and Jernikoff report that, in an attempt to substitute for the biologic method of Zondei-Aschheim a chemical test for the detection of the hypophyseal hormone in the urine, Rodcutt made experiments with numerous reagents without finding an entirely satisfactory test. Then Maniolo described a simple seroreaction for the diagnosis of pregnancy, with which he obtained correct results in from 92 to 96 per cent of the cases. To 0.3 cc of fresh, clear serum he adds 1 cc of a 2 per cent aqueous solution of theobromine sodiosulphate, shakes the mixture and then adds a drop of a 0.2 per cent alcoholic solution of Nile blue and again stirs the mixture. After from several minutes to an hour the mixture decolorizes and appears yellow or pinkish yellow if the serum is from a pregnant patient. However, if the woman is not pregnant the serum mixture is blue, bluish or pinkish blue. The authors investigated the reliability of this reaction by testing the serums of pregnant and of non-pregnant women seventy-five in all. But in spite of a careful technique their results were unsatisfactory. The color nuances varied considerably and a clear differentiation between positive and negative reactions was impossible.

Foreign Bodies Left in Abdomen During Operations
Experiments with Contrast Gauze—Grunstein points out that during operations foreign bodies are occasionally left behind. In case of clamps rings or other metal objects a detection by means of roentgen rays is possible. But small gauze pledgets that are most frequently overlooked cannot be detected with the roentgen apparatus. Various methods have been recommended to prevent gauze compresses from being left behind or, if they have been overlooked to make them detectable by roentgen rays, namely attaching a metal ring or a bronze wire or a leaden weight to each compress. However, all these procedures have their disadvantages. Grün had the idea to prepare a special gauze for use in operations. Threads impregnated with thorium hydroxide, are woven into the gauze. These threads produce a

shadow in the roentgenogram, especially when they are massed together as is the case in a compress. This so-called contrast gauze may be washed, sterilized, soaked with iodoform or other substances, or returned for a time in a body cavity, without losing the quality of being impermeable for roentgen rays. It has no irritative effects.

- Primary Tuberculosis of Skin C. Guldberg—p. 1235

Case of "Testicular Tubular Adenoma of Ovary"—Including Popoff's case, Berner's makes the sixth case of testicular tubular adenoma of the ovary reported in the literature. As in the cited cases of Pick, Schickel, Neumann and Strassmann the testicular portion of the tumor is sharply defined from the ovarian and of the same yellow color as the testis parenchyma and the smaller ovarian portion of the tumor rests almost like a hood on the testicular portion. The signs of hermaphroditism in this instance gradually disappeared after excision of the ovary. He is inclined to ascribe the testicular part of the tubular adenoma to a shifting in the person's chemical milieu (Goldschmidt).

Incidence of Goiter and Occurrence of Iodine in Vestestranden in Sogn—Iversen et al. found an iodine elimination in twenty-four hours of from 154 to 345 γ in the urine of men in this isolated Norwegian village of 500 inhabitants of whom about 70 per cent have goiter. The iodine concentration in the urine varied between 11 and 35 γ per hundred cubic centimeters. Earlier investigations in the goiter district of Sandvåg revealed an average iodine elimination of from 29 to 87 γ in twenty-four hours. In the goiter free district of Vik in Sogn the average was 173 γ in twenty-four hours. The iodine content of the water in Vestestranden is neither remarkably high nor remarkably low. Samples of the soil gave iodine values of between 4 and 80 γ per hundred grams. The diet consists mainly of meat and potatoes with a little salt fish. The drinking water is poor. The cause of the goiter in the region is to date unknown.

Venereal Granuloma—In Hval's patient, a sailor previously treated in several places for secondary syphilis there was the typical picture of venereal granuloma. Microscopic examination of the granulation tissue revealed partly in the large mononuclear cells partly in groups outside the cells the Donovan bodies characteristic of this disease. Infection had occurred in South America. Venereal granuloma has not before been observed in Norway.

Subacute Inguinal Lymphogranulomatosis—In the four cases reported, microscopic examination of the lymph nodes disclosed a granulation tissue with abundant cells. There were numerous small, irregularly defined abscesses, often with central necrosis. The micro abscesses were surrounded by a border of epithelioid cells with occasional cells with two or three nuclei and also occasional Langhans giant cells. The abscesses presented a polymorphic picture. Hval says that diagnosis cannot be based on the microscopic changes alone. He considers Wilhelm Frei's intracutaneous antigen reaction of great value in the diagnosis. This reaction was positive in the four cases.

Primary Tuberculosis of Skin—In Guldberg's patient, a boy aged 13, of a healthy family there were continued granulation and suppuration in one of three wounds on the knuckles of the left hand following a trauma. A lymphadenitis developed in four or five weeks in the left forearm and two weeks later in the left axilla and gradually took on the picture of a tuberculous lymphadenitis with formation of fistula. Tubercle bacilli were demonstrated in the wound and in the abscesses of the lymph nodes. Clinical and roentgen examination of the lungs showed no signs of tuberculosis. The Pirquet test was positive three months after the occurrence of the wound. The case is considered as primary tuberculosis of the skin with regional lymphadenitis.

THE PRESENT CONSIDERATION AND CARE OF THE COLON*

JOHN A. LICHTY, M.D.
CLIFTON SPRINGS, N. Y.

It is my purpose in this contribution to call attention more specifically to those functional disturbances of the large bowel which are frequently the cause of considerable concern to the patient and annoyance to the attending physician. It is not my purpose, on the other hand, to discuss chronic ulcerative colitis. That condition is at present receiving intensive study, especially in the bacteriologic laboratory, and a voluminous, controversial literature is about the only definite result as yet.

Among the functional disturbances of the bowels are certain irregularities due to an atonic condition at times or, again, to a spastic condition of the colon. With these disturbances of motility there are also secondary disturbances, and these together may gradually develop a mild irritative condition of the mucous membrane with a production of stringy mucus, ordinarily called mucous colitis, and attributed to a neurogenic origin. There may gradually develop a more or less catarrhal condition with a production of flakes or clumps and strings of mucus containing innumerable leukocytes. Others of these functional disturbances are dilatation and sagging of certain portions of the colon, due either to congenital defects or to developmental changes. On account of the attempt at a compensatory restoration of function, extraperitoneal folds are formed. Also on account of continual traumatic insult there may develop weblike adhesions.

With all these disturbances which may take place in or about the colon the patient almost invariably develops a certain degree of invalidism characterized by psychic and neurotic symptoms. Other symptoms more constant and probably more significant are irregularity of the bowels, such as constipation and occasionally diarrhea, an accumulation of gas in the abdomen, producing an annoying borborygmus, irritation and soreness in the course of the colon and an occasional pain and bearing down sensation especially in the lower part of the abdomen. The pain may be very severe especially before there is a stool usually consisting mostly of mucus. The pain may occur suddenly and be cramplike in character mimicking acute appendicitis, gallstone attacks, renal colic or duodenal ulcer.

Such misleading symptoms demand careful consideration as occasionally unnecessary operative procedure is undertaken. The patient gradually develops a food

phobia and subjects himself to an unnecessarily rigid diet. This leads to loss of weight which in turn aggravates the original condition, forming a so-called vicious circle. It is not unusual for the patient to become bedfast.

The problems which such a case presents are numerous. Not the least among these is that of a differential diagnosis. The case study must be complete. It is an unfortunate mistake to proceed with a long course of treatment—and it usually is a long one—on the assumption that the condition is only an intestinal neurosis, and find later that a serious organic lesion has been overlooked, but it is even more unfortunate to take up surgical intervention with no organic lesion warranting an operation. The chief concern, therefore in the consideration and care of the colon is that the diagnosis will represent the real condition present and will suggest the course of treatment. There is probably no diagnostic procedure more helpful in determining the true condition of the colon than the roentgen examination. It shows the position of the colon and whether it is free or fixed. With the judicious use of belladonna or some of its derivatives, and by repeated gastro-intestinal series and barium enemas, the roentgenogram reveals, among other things, the abnormally spastic or atonic colon and excludes organic changes.

Before undertaking the treatment of these patients with chronic disturbance of the colon, one should obtain a certain concept of the state of the nervous system. This is accomplished largely through a painstaking, careful history. Also the disturbances of the secretory activities of the alimentary tract should be known. Such information as is obtained from gastric analysis, duodenal drainage and examinations of the stools is helpful. It is desirable to make all these studies in a definite and concise order before the treatment is planned. Uncertainty on the part of the physician will soon lead to an unfortunate psychologic reaction on the part of the patient. Every effort should be made to overcome anxiety and nervous strain. The diet should be nutritious so as to maintain a normal, or somewhat higher than normal body weight for a time. The diet should not be bulky, coarse and irritative when the case is first undertaken. In the early stage of the treatment it is well to puree the vegetables and stew the fruits. Abundance of fat in the way of butter, cream and olive oil should be given. Irritating cathartics should be avoided; they are not necessary if fats and fluids are given in sufficient quantities. If medication is necessary, on account of constipation, it should be determined largely by the degree of spasticity of the bowels and the acid content of the gastric juice. Constipation with a spastic bowel and a high gastric acidity yields more readily to an alkaline laxative, such as magnesium oxide with the addition of belladonna or its

* Read before the Section on Gastro-Enterology and Proctology at the Eighty First Annual Session of the American Medical Association, Detroit, June 25, 1930.

derivatives, whereas the atonic bowel with low gastric acidity will yield more readily to bitter laxatives, such as the cascara preparations with the addition of nuxvomica and its derivatives. As the symptoms of the irritable colon disappear the diet should be changed by allowing more roughage and a more even balance of carbohydrates and fats. This will usually control the irregularity of the bowels that gives such concern. Frequently patients with an irritable or a sluggish colon will resort to large and repeated enemas.

It is unfortunate for these patients to get into the habit of flushing the colon, as is so often the case. This procedure has become a kind of fetish, and it seems to have come to such a pass that in any representative community the citizenship may readily be divided into two distinct groups—those who wash their colons regularly, and those who do not. It might

Fig 1—Barium enema entering colon

be well for the medical profession to determine what of good there is in this procedure and to protect the laity against certain fatiguing, unnecessary and expensive manipulations.

In a reply to a follow-up letter, recently received, this report is given: "Extensive internal irrigations have been used since my return home. I am not clear that they did me a great deal of good, though it seems a very rational and practical thing." The idea prevails, especially among the laity, and among some physicians, that the colon is a constant source of danger because of a supposed possibility of infection from pathogenic micro-organisms, or from absorption of toxic poisoning, and it must therefore be responsible for many human ills. For this reason the colon has become the field of exploitation and experimentation to an amazing degree. No more radical measure in medicine has been offered than that of some two decades ago, when Sir Arbuthnot Lane advocated the total excision of the colon in certain abdominal disorders, among which were chronic colitis with adhesions of the colon. Fortunately, the profession did not long follow this procedure. Partial colectomy came next with multiple short circuitings, and finally, it seems, colonic lavage became the vogue. This is a procedure which has been known for centuries but it comes this time with an intricate technic, requiring complicated armamentarium. Consequently, there are at present doctors, nurses and attendants who permit themselves to be designated as colon specialists. It is not unusual to find under the plate glass of the dresser in a hotel room a card on which these colon experts announce their willingness to lavage the colon before the guest retires. The degree of their efficiency is usually measured by the distance these specialists can thread the colon with a suitable tube, the amount of fluid they can introduce, and perhaps the size of the fee they exact.

But ours is not the only generation responsible for such exploitation of the colon. In an address given

"by Dr Arthur I. Hurst¹ before the Harrogate Medical Society, England, Nov. 26, 1921, entitled "The Sins and Sorrows of the Colon," he says "Pliny A. D. 77, tells how the Egyptians learned to wash their bowel from observing the habits of the ibis. He washed the inside of his body by introducing water with his beak into the channel by which our health demands that the residue of our food should leave. It is cruel to deprive the ibis of his claim to this epoch-making discovery, but the truth must be told, the ibis does not give himself a colonic douche, but after washing his beak in water he oils it in his preen-gland, which is situated near the anus, in preparation for preening his feathers." In the sixteenth century the enema reached the height of its popularity. It is recorded that Louis XIV received several thousand intestinal douches in the course of his life and that the pious Duchess of Alva treated her sickly son with enemas, in emulsion of religious relics but unhappily they failed to save him.

There is no doubt that in certain conditions a simple enema of warm salt solution, or one containing certain medication, is indicated and, when properly given, is a valuable therapeutic measure, but my contention is that it is given undue importance at times, and at times may do great harm because of grave pathologic conditions and unnecessary manipulation. Any fluid, even though it has the consistency of the ordinary barium enema, after it once passes the anal sphincter, will pass easily up the sigmoid and descending colon, across and down to the caecum regardless of the position of the body of the patient. This is easily demonstrated as shown with the roentgenograms taken by Dr C. Harvey Jewett, of our staff, in which he scheduled the rate in minutes of a barium enema as it transverses the colon from the anus to the cecum, using a small, hard rubber anal tip according to Hurst's suggestion, which delivered the enema just inside the anal sphincter.

Another film will show the position of an ordinary, so-called colon tube when the attempt is made to insert

Fig 2—Barium enema after one minute

it at the anus and pass it through the course of the large bowel. It is true that, with proper manipulation, a soft rubber tube may be passed through the sigmoid and probably to the splenic flexure, but what is to be accomplished by such a procedure? If the fluid goes up to the ileocecal valve and beyond it, without the distressing manipulation, what is to be gained by attempting to thread the colon? Some of the colon enthusiasts maintain that certain vaccines or micro-organisms cannot be "planted into the cecum except by being delivered through a rubber colon tube properly placed." It is my impression that any vaccine broth with no heavier consistency than that of an enema of liquid petrolatum or barium sulphate can be passed into the cecum with ease just as soon as the tip of the syringe nozzle is placed inside the anus. For these

reasons and others I feel that the attempted vaccine "implantations" are an unnecessary hardship to the patient. I am also convinced that in certain cases the irritation subsequent to the manipulation of the tube in the rectum and lower sigmoid, together with the distention brought about by quarts and sometimes gallons of water, may do harm.

In a paper presented by Drs. Friedenwald and Feldman before the American Gastro-Enterological Association at Atlantic City, last May, they concluded from experiments on animals that the prolonged use of even the simplest form of enema proved slightly irritating to the bowel. However, oil showed no effect. Weak solutions of chemicals of different forms produced changes ranging from slight inflammation to ulceration. They also reported a tendency to a thinning of the intestinal wall and a loss of elasticity.

Fig. 3—Barium enema after one and a half minutes

Figure 8 shows the pathologic changes in a descending colon removed at autopsy from a patient who had an ulcerative and hemorrhagic colitis. If we had succeeded in distending this colon in a flushing process, as suggested, we would, without doubt, have produced a perforation long before it occurred.

The intestinal flora may be readily modified or changed by alteration of diet. A low carbohydrate diet for a few weeks, or, again, a low protein diet for the same length of time, may result in a more definite change in the intestinal flora, when such a change is indicated, than the feeding of certain micro-organisms or the administering of daily cathartics, or the extensive colonic flushings occasionally advocated.

It is encouraging to have this opinion corroborated by so able an authority as Dr. Arthur F. Hurst, physician to Guy's Hospital, already quoted who says, in addition, "It is of great importance that the douche should be properly instituted. Nurses are always taught to pass the tube as far into the rectum as possible, and are rarely satisfied unless 12 or more inches have been introduced. Until comparatively recently, I understand, this was the general practice, but the pelvic rectal flexure, where the freely movable pelvic colon joins the fixed rectum at an acute angle, is $4\frac{1}{2}$ inches from the anus, and it is a physical impossibility to pass a rubber tube beyond the flexure excepting through a sigmoidoscope which has been manipulated through the flexure. This was proved long ago by surgeon Goodhart, in the postmortem room in 1900 and again more recently I demonstrated the same fact with the x-ray, which show that the tube turns back when the flexure is reached and curls up in the rectum." This experience coincides exactly with our own as demonstrated by a roentgenogram taken with the colon tube carefully inserted supposedly to the extent of the entire length of the colon.

The teaching in medical schools and in training schools for nurses with reference to giving enemata

should be more specific than it appears to be. It should be taught that the difference between an ordinary enema and the so-called high enema is not determined by the length of the rubber tubing passed through the anus but by the amount of fluid used and the length of time allowed for it to flow in and out.

It might be said that the natural condition of the colon is to be more or less full, and any attempt to keep it empty by strong laxatives or large enemata or flushings is based on a misconception of the function of the colon and will be likely to cause harm. The colon should have the same consideration and care in relation to disease as any of the other viscera and should not receive any more abuse than any other organ when there seems to be a dysfunction.

ABSTRACT OF DISCUSSION

DR. SARA M. JORDAN, Boston. Dr. Lichty spoke of the difficulty of diagnosis of colonic functional disease. The difficulty is great. In one point I would differ with him. He said that he thought it was a little more unfortunate to operate for a surgical lesion and find none than to carry on a long medical treatment for colonic functional disease and then discover a serious organic lesion. I have been so trained by my surgical associates, medical-minded as they are, that I find myself more chagrined to have carried on the long medical procedure in the presence of a serious organic lesion requiring surgery than to have had a patient operated on when no organic lesion was found and then to have carried on the medical procedure for a functional disease. The symptoms of colonic functional disease mask and induce and increase symptoms of organic disease. I have in the past year collected a small group of cases in which the symptoms of diaphragmatic hernia were undoubtedly induced by functional colonic disease. They showed a definite, large hernia which could be kept symptom free if treatment of the colon and a mild hyperchlorhydria were carried out. They were not good surgical risks and could not be operated on, but if the colon was not distended and functioned normally those patients had no symptoms from the diaphragmatic hernia. The pernicious and the baneful effect of colonic irrigations cannot be stressed too much.

In the first place, it is an unnecessary intervention and the trend of modern therapy in other conditions, such as in heart disease has been against and away from unnecessary intervention. Secondly, the loss of body fluids which must occur with colonic irrigations or with any forced stimulation of the colon is, I believe, an important consideration. It has recently been shown how important the loss of gastric and pancreatic secretion is to a lesser degree. I

Fig. 4—Barium enema after two and a half minutes

think the loss of fluid from the colon which follows colonic irrigation should likewise be an important consideration in the discussion of this form of therapy. The distention and loss of tone that must occur from colonic irrigations and does occur as we have observed in cases referred to us is also a serious consideration and should be used as an argument against this vogue.

DR. JOHN G. MATEER, Detroit. I am heartily in accord with everything Dr. Lichty has said. As to the differential diagnosis of these functional colon conditions I think it will be agreed that there are still too many so-called chronically inflamed appendices and relatively thin-walled noncalculous

gallbladders being removed because colon distress is attributed to pathologic changes of the gallbladder or appendix. This error could be materially reduced if further emphasis were placed on the characteristic clinical picture of the irritable colon. Time does not allow a development and illustration of this point. As regards treatment, extremely satisfactory therapeutic results can be obtained in a high percentage of these irritable colon cases provided the diagnostic analysis is complete and the therapeutic program is correspondingly comprehensive, and provided, finally, that the cooperation of the patient is obtained. In my experience, the most important single point in the successful treatment of these patients consists of a painstaking analysis of the patient's nervous status, followed by the elimination of those faulty habits which tend to increase the general nervous irritability which, in turn, is reflected out through the autonomic nervous system to the wall of the alimentary tract. In this connection it is absolutely essential to eliminate such habits as hurry, overwork, worry, the so-called anxiety state, the use of external stimulants, such as coffee and tobacco particularly, abnormalities in the sex life, which in certain women patients constitute an important factor in maintaining the nervous tension, and other similar habits. Dr. Lichty has simplified the discussion of diet in these cases, and properly so because so many of these patients come to the physician with an elaborate, fixed idea about some diet food, which has to be eliminated. I am heartily in accord, also, with his criticism of the indiscriminate use of colonic irrigations. As to drug therapy in these patients,

of feces. Secondly, it requires a long time to give a colonic irrigation. It is not a matter of getting water to the cecum and out again; any enemata will do that. That is why an enemata may be a bad thing. The colon should never ordinarily be emptied so completely as that, and that is an objection to frequent irrigations. Irrigation of the colon must be done slowly. I use the two-tube method because I don't want the colon overdistended. We go about it very slowly, placing the bag so that there is a level of the water of about a foot and a half or two feet above the patient to make very low pressure. It takes me from three quarters of an hour to an hour. Are these colonic irrigations of any use? Yes. Sometimes after a lot of soaking I get out nasty mucus. I have bottles of preserved mucus and great crabs of the intestine up to 18 inches in length, dark colored and vile-smelling when expelled, and this does not come down at first, and it rarely appears in the feces so far as I can see. If these mucous substances never appear in the feces, what becomes of them? They must be absorbed into the system and they are poisons. But I would sound a warning; irrigations should not be abused. Using them every day is a serious mistake.

DR. L. J. HIRSCHMAN, Detroit: I agree most heartily with the warning, Dr. Lichty has uttered about the chain-store system and the corner-cleansing stations for the colon. It has come to a point where standardization has been carried a little bit too far. He stated that a complete roentgen examination is made, but he did not specify that, besides the making of serial plates,

Fig. 5—Introduction of a colon tube supposed to have passed to the cecum.

Fig. 6—Barium passes through the tube shown in figure 5.

Fig. 7—Barium enema administered through an ordinary anal nozzle in a patient with redundant sigmoid loop.

I have found that small doses of phenobarbital and the time-honored remedy, belladonna, are particularly helpful in the early therapy. I should like to emphasize the fact that, although there is probably no medical condition confronting the physician which requires greater patience than the handling of some of the more difficult cases, nevertheless the therapeutic results more than justify the time and effort expended.

DR. WALTER A. BASTEDO, New York: A barium enema does not represent the normal state of the colon; it represents the effect of an enemata on the colon, with extreme distention, a condition in which the colon is not ordinarily found at all. Haustral contractions are not peristaltic waves, though often thought to be so by those interpreting them. Haustral contractions may last a half hour or an hour. I have seen them last a long time in an animal with its abdomen opened. They are retarding contractions of the colon. They keep back the contents of the colon. They prevent movements all the time as the material comes down from the ileum into the colon; therefore they are not peristaltic waves at all. They are fixed, spastic waves. On the other hand, peristaltic waves are driving waves and in the roentgenograms are distinct from these. I agree absolutely with Dr. Lichty about colonic irrigations. I am an advocate of colonic irrigations because they do something, just as I am an advocate of lavage of the stomach in the proper place. Colonic irrigations are not usually given well. In the first place, the patient must have had the morning movement or an enemata should be given to produce the movement, because a colon cannot be properly irrigated if the lower bowel is full

he includes a careful fluoroscopic investigation with the patient turned from side to side not only after a meal but also after a sufficient injection of barium into the bowel to outline it without the distention about which Dr. Bastedo properly utters a warning note. He is right that a barium enema represents a distended colon and not a normal one. However, often one must inject enough barium from below to get a complete filling, so that on manipulation one can discover whether there are any filling defects which are on a different plane from the anterior-posterior through which plane most roentgenograms are made. Most of the patients who come to the physician suffering from colonic dysfunction are women, and a large majority of those women have had, at some time, an abdominal operation, and most of those women have been operated on by physicians under general anesthesia when in order to have a clear field, whether the patient was in a Trendelenburg position or not, quantities of gauze were used to "prick off" the intestine. If any one thing insults the delicate serous membrane, it is rubbing it, straining it, pushing it with gauze, whether it is rough, wet or dry, and many women who suffer from colonic dysfunction improperly interpreted and call on the colonic laundries for assistance without getting good medical advice are not suffering so much from integral disease of the bowel wall as from abnormal irritation from some insult offered by a well-meaning surgeon in the course of an abdominal operation. I am a surgeon myself. I feel that the gauze should be protected with rubber dam and a spinal anesthesia used so that the bowel lies where it is put and then some of our friends will not have so many cases of

colonic dysfunction. The male patients and many female patients, who have not enjoyed the luxury of an abdominal operation, owe their crises of colonic dysfunction to legislative enactment. Since the Eighteenth Amendment has come into force, many people who, previous to that time, did not feel the need of alcoholic stimulation now believe that "forbidden fruits taste sweetest" and are now "making their own." As a result of the irritating quality of alcoholic fluid sent into the colon, they not only have their digestion impaired but their colons are irritated, and many cases of disturbed colon or colitis seem to occur.

DR JULIUS FRIEDENWALD, Baltimore. We have been trying to discover the effect of colonic enemas and irrigations on animals and we have carried out at our clinic at the University of Maryland some experiments in which we have studied the colons in dogs that have been subjected to enemas over long periods. We have noted that the continued use of enemas is harmful to the bowel and is likely to induce a variety of colonic disturbances ranging from a mild to a more or less severe type. Water, oil and acriflavine hydrochloride (1 3,000) produce less irritation, and soap-suds and chemicals, even in weaker solutions, may cause extensive ulceration.

DR SEALE HARRIS, Birmingham, Ala.

The most important thing in the treatment of most colonic conditions is to let the colon alone and treat the patient. Much harm has been done by continuing smooth diets too long. Regarding the etiology of this condition, I think it is important to consider the vitamins, about which some people say nothing is known, but there is a great deal that is known about vitamins. Usually the people who say nothing is known about vitamins are those who really do not know anything about them. Sugar saturated, vitamin

starved Americans living on white flour bread, white rice, white potatoes, lean meats, oleomargarine butter and sugar saturated desserts and soft drinks are prone to develop disturbances of the colon. Most persons live on such a deficient vitamin diet and as a result they have intestinal infections of all kinds. I agree with Dr Hirschman that if people could be taught to forget bran, they would be a lot better off in these cases. Though I think it is not the smooth diet that is needed so much as a well balanced diet, one rich in vitamins consisting largely of fruits and vegetables, milk, cream and butter and meat once a day. Cut out the sugars entirely and reduce the bread. In other words, a low carbohydrate, rich vitamin diet. It is also important to teach the patient with disturbances of the colon how to live, work eight hours a day, not too much but work enough, with eight or nine hours in bed at night and a rest at noon. As Dr Weir Mitchell has said, the best doctors of all times have been those who regulated the lives of their patients so that they could be restored to health and maintain health afterward.

DR JOHN A. LICHTY, Clifton Springs, N. Y. The main object of the paper was to call attention to the rather intensive irrigation of the colon which is done in a somewhat promiscuous

Fig. 8—Descending colon recovered in a case of hemorrhagic colitis with perforation.

way for conditions in which the colon has no part. I am indebted to Dr Friedenwald for referring to his recent paper, read at Atlantic City, in which the results of long continued, and large irrigations of the colon of the dog are reported. It seems that an irritation of the mucous membrane and loss of tone of the colon resulted. The conclusion is that such irrigations of the human colon may do more harm than good. With reference to Dr Jordan's remarks, I would say that while the chagrin to the physician may be great when the pathologic condition in the abdominal cavity that warrants operative procedure is overlooked, it does not compare, sometimes, with the pain and suffering which these patients endure who have repeated laparotomies followed by extensive adhesions. With reference to the difficulty in interpreting the real condition of the colon with the barium enema to which Dr Bastedo has called attention, one must take a conservative attitude in drawing conclusions from the test. The patient should have repeated barium enemas under different conditions, at one time after being under the influence of belladonna to the physiologic limit and again without belladonna. The "vile stuff" in the colon to which he refers is the normal or usual content of the colon, but, unfortunately, nature has so provided that this is not necessarily absorbed from the bowel and does not need to be washed out to the extent of 95 per cent to insure health and well being. There are conditions in which the colon should be emptied by lavaging, but it should be done under careful supervision, with a nurse or an attendant, if desirable, but the enthusiasm for washing until the last remnant of feces or the last bit of mucus disappears should be guarded against. It may be dangerously fatiguing in certain cases. The difficulty of furnishing the colon patient with sufficient vitamins, as suggested by Dr Seale Harris, should not be an insurmountable one, so long as the green vegetables and fruits can be purged.

SPONTANEOUS PNEUMOTHORAX *

J. P. PALMER, M.D.

AND

ROBERT B. TAFT, M.D.

CHARLESTON, S. C.

Spontaneous pneumothorax is a term that is generally used to indicate the presence of air in the pleural cavity from an internal cause. Some writers, however, consider as spontaneous only those cases in which there is no associated pathologic change of the lung (the so-called idiopathic pneumothorax). In this paper we shall consider those occurring from any internal cause.

Spontaneous pneumothorax, taken as a whole, is not an uncommon occurrence. However, the so-called idiopathic pneumothorax is rare, there having been only about seventy cases reported, and in no instance was there a report of more than four cases by any one man. There are five case reports included in this paper of patients in whom no pathologic change of the lung was demonstrable nor any history of previous lung trouble, and the subsequent history shows them to be normal in health. One other case gave no history of previous lung trouble and the normal side at the time of examination showed no evidence of disease. However, we were unable to repeat the examination after the collapsed lung had resumed its normal state. All of these are therefore considered to be definite idiopathic cases.

The most common etiologic factor responsible for the development of this condition is tuberculosis. The records show that this is the cause in about 80 to 90 per cent of the adult cases and 40 to 50 per cent of the cases in children. The difference here is due to the fact that there are more cases in children than are

* Read before the Section on Radiology at the Eighty First Annual Session of the American Medical Association, Detroit, June 2, 1930.

crused by the acute infectious diseases. Among the other underlying causes are empyema, gangrene, bronchiectasis, infarct, pneumonia, emphysema, new growths and very rarely the action of gas forming bacteria in a pleural exudate.

As the name implies, no cause is known for the idiopathic group. However, there are various ideas put forth as to the cause. Some state that these cases are probably due to a tuberculous infection in which there are no physical signs obtainable and no positive roentgen evidence is obtainable. The theory has also been advanced that a tuberculous process is present and causes the rupture and that the collapse and rest of the lung allow this process to heal entirely without leaving any scar formation. Others think the condition due to the rupture of an emphysematous bleb on the margin of the lung. Still others think that probably there has been some inflammatory condition causing adhesions between the visceral and parietal pleuras and that unusual exertion causes this adhesion to be torn loose, thus causing a rupture. This type of case rarely ends fatally, and it will be difficult ever to establish a real cause.

The exciting causes are coughing, sneezing, laughing, vomiting, hiccups or muscular strain, or there may not

Fig. 1 (case 1).—Appearance of chest. *A*, twenty-four hours after onset showing complete collapse of the left lung but very little displacement of the mediastinum. *B*, four weeks after attack, normal.

be an exciting cause. The condition often occurs while the patient is at rest or even asleep.

If the condition occurs as the result of a preexisting tuberculosis or other inflammatory disease, the onset may be insidious and the patient may not know when it happens. This is due to the presence of adhesions and to the fact that the lung cannot collapse suddenly or completely. On the other hand, if there are no adhesions the onset is sudden and there is a sharp, stabbing pain in the chest followed immediately by a feeling of suffocation, air hunger and a feeling of impending death. There is usually a marked cyanosis and often collapse. There is also a marked orthopnea and the patients cannot lie down until the acute stage is passed. When able to lie down they usually lie on the unaffected side. There may be a distressing cough, but this is not a constant symptom.

After the first twelve to twenty-four hours the character of the pain changes to a dull pressure sensation, which the patients describe as a heavy weight on the chest. They become more comfortable, the dyspnea becomes less marked, and unless complicated by fluid there are no symptoms after a few days.

If seen early, the patient is cyanotic and there is an expression of extreme anxiety. The alae of the nose

are dilated and the effort to breathe is noted. The respirations are shallow, rapid and forced, and the accessory muscles of respiration are brought into play.

On examination the following signs are usually found. The affected side is larger than the unaffected. The intercostal spaces are pushed outward. There is little or no motion on respiration. The cardiac impulse may be seen to be displaced. There is diminished or absent fremitus. The cardiac impulse is felt and is displaced away from the affected side.

The percussion note is tympanitic and the tympanic area is larger than the normal lung. The percussion note may change when the patient opens and closes his mouth, owing to the free communication of the intrathoracic air with the outside air. The cardiac dullness is displaced or in some cases cannot be elicited. If fluid is present there is a corresponding area of dullness, which changes completely with a change of position.

The breath sounds are suppressed or entirely absent. If they are present, breathing is amphoric in type. Voice sounds are also diminished or absent. A succussion sound is often heard even when there is no evidence of any fluid present. The con sound is a nearly constant sign and is one of the most significant.

The roentgen examination should be made by both fluoroscope and film. The upright position is the most satisfactory, as it is easier in this position to determine the presence and amount of fluid. The appearance will vary according to the degree of collapse. The air shows as a very clear area in which there are no lung markings. If adhesions are present they show as irregularly expanded areas, held to the chest wall, and they are denser than the surrounding collapsed areas. The mediastinum is shown displaced away from the affected side. If fluid is present it shows as a dense shadow at the lower part of the chest, which changes position as that of the patient is changed. By shaking the patient one can form waves and notice them pass through this fluid. Waves are noted also as synchronous with the beats of the heart.

The duration of the disease depends on the underlying pathologic changes. The uncomplicated cases usually clear up in from two weeks to two months but may last much longer. One case is reported that lasted for sixteen months and then cleared up completely. Another case has been known to exist for twenty years.

Fluid rarely forms in the cases in which pulmonary changes cannot be demonstrated but is common in the tuberculous cases. The fluid may be, and usually is, a pleural effusion but may at times be blood from a ruptured vessel. If the fluid becomes infected, the course of the disease is greatly prolonged.

The prognosis in the tuberculous cases is grave, the mortality being about 70 per cent. In several cases of known tuberculous origin, the tuberculosis has been completely arrested by the collapse and rest of the lung.

The prognosis in the cases without demonstrable pulmonary changes is favorable, only one of the fifty-eight cases studied by Russell and Reisman ended in death.

Bilateral pneumothorax is nearly always fatal and the patients die within a few hours.

Recurrence of the pneumothorax is not uncommon. One case is reported in which there were eleven recurrences. In another there were eighteen recurrences during a period of eight years, all of which were of the right lung except one.

TREATMENT

As it is necessary for the fistula to close before the lung can expand, the patient should be kept quiet, the cough should be controlled as much as possible, and deep inspirations that tend to aspirate infectious material into the pleural cavity should be avoided. This can be accomplished by strapping the side, which is the only treatment necessary in the mild cases with no fluid.

In the cases presenting a moderate amount of fluid, if the symptoms are not severe it is best to delay

Fig 2 (case 2)—Appearance of chest A twenty four hours after onset B after twelve weeks normal

drawing off the fluid until the fistula has had time to close. On the other hand, when there is a large amount of fluid immediate tapping may be necessary to relieve pressure symptoms. In these cases it is best to draw off only a small amount of fluid at a time because of the danger of reopening the fistula and allowing infectious material to enter the pleural cavity.

In cases in which a frank purulent exudate is present, a thoracotomy is resorted to.

In some of the cases in which the opening is valvular in type, even though no fluid is present, the intrathoracic pressure may be raised to such a degree that the pressure on the heart is dangerous. In these it may be necessary to insert a cannula and remove some of the air.

REPORT OF CASES

CASE 1—E M S, a white man aged 32 a toll gate keeper who had had good health, without serious illnesses, tuberculous association, influenza or pneumonia, had had an unexplained mild diarrhea about one month before which had cleared before the present trouble. May 28, 1929, while standing with his arm resting on the side of a car and talking, he was seized with a sudden stabbing pain in the back at the angle of the left scapula, which then radiated over the whole chest. The pain was excruciating for about two hours when it was relieved by acetylsalicylic acid. The pain was accompanied by a marked dyspnea. After the effect of the acetylsalicylic acid had worn off the pain was never severe except when the patient attempted to lie down. For about a week he was unable to lie flat without severe pain. The patient never had any cough and after a few hours the dyspnea was not marked. He made an uneventful recovery and was apparently perfectly well in four weeks. He has had no subsequent trouble.

CASE 2—H W M, a white man, aged 38 or 39 a plumber, who had always had good health without lung trouble or association with tuberculosis developed a sudden acute pain in the lower part of the left chest, dyspnea and profuse sweat while he was seated at the table at home without any exertion. After a few hours the acute symptoms passed and the patient was comfortable except on coughing or deep inspiration. A roentgenogram taken Nov 3 1927 the second day, revealed no fluid

He had no subsequent trouble and was back at work in about two months. The lung was not completely expanded for more than three months.

CASE 3—A T C, a white man, aged 26 a clerk, had had no tuberculous association, and had always had good health except that about two years before he had had a sudden onset of acute pain in the left chest. This was thought by his physician to be pleurisy. On the second day there were signs of effusion. This rapidly increased and on the third day the left chest was filled with the effusion. The chest was tapped at this time and a small amount of fluid was removed which had the appearance of fresh blood. Two days later a large amount of fluid of the same quality was removed. No cause was ever found for this condition. In about five or six weeks the patient had fully recovered and there were no physical signs in the chest. Feb 17, 1928, after having gone to bed feeling perfectly well, the patient was awakened by an acute pain in the lower right side and he developed a severe dyspnea. Both were less severe the next day when he reported to his physician. The physical signs were typical of a pneumothorax, and roentgen examination confirmed the diagnosis. No fluid was formed, and March 2 the lung was about one-half expanded. April 3 the lung was shown to be completely expanded and otherwise normal. There was no evidence of any pathologic change. Since then he has been back at work without any evidence of trouble. In view of this attack, it is thought probable that the previous attack was a spontaneous pneumothorax also in which there was a rupture of a vessel of considerable size, thus accounting for the large amount of blood in the pleural cavity.

CASE 4—H D R, a white man, aged about 25, who worked at a filling station, had had good health, without previous lung trouble, association with tuberculosis and no recent illnesses. The patient had been drinking and had become nauseated. He was leaning against a tree in the act of vomiting when he was seized with a severe pain in the lower right side of the chest and back. He went home to bed. The pain continued and dyspnea developed. A roentgenogram the second day showed the right lung to be completely collapsed. The right chest was half full of fluid and the mediastinum was displaced to the left. There was no evidence of involvement of the left lung. The patient's chest was tapped and bloody fluid was removed; there was a slow expansion. There have been no check-up roentgenograms made since the lung has returned to normal. However, the patient, who has since left Charleston, has not reported any

Fig 3 (case 3)—Appearance of chest A Feb 18 1928 complete collapse of right lung and considerable displacement of the mediastinum to the left right side of diaphragm displaced downward B March 2 right lung about one half expanded C April 3 right lung completely expanded and normal in appearance and mediastinum returned to normal position

symptoms of lung trouble and is apparently in perfect health and continuously at work.

CASE 5—A M S, aged 37 a clerk who had had no recent illness, no previous lung trouble and no tuberculous association while seated at a desk had a sudden acute pain in the right side of the chest with loss of consciousness for a few minutes. The acute pain passed after a few minutes and after taking acetylsalicylic acid but the patient has had some pain ever since the onset (forty-eight hours). Symptoms at forty-eight hours were pain in the right side of the chest exaggerated on deep inspiration and marked dyspnea on exertion. Dec 7, 1929, a

roentgenogram showed a complete collapse of the right lung. December 14 a fluoroscopic examination showed a slight expansion. December 30, fluoroscopy showed the lung to be about one-half expanded, more at the base than at the apex. There was a very small amount of fluid. Jan. 6, 1930, fluoroscopy showed a complete expansion except for a small area at the apex. The film taken January 10 showed a complete expansion. There has been no evidence of any definite pathologic changes in the lung. The patient was symptom free and there were no physical signs.

COMMENT

These cases are reported because of the unusual number in one clinic in a relatively short time, also because of the fact that although in most cases the collapse of the lung was complete, the symptoms were unusually mild and of less than the average duration.

The most unusual feature is the fact that there were two cases in which there was a massive hemorrhage

Fig. 4 (case 4)—Appearance of chest twenty four hours after onset right lung completely collapsed and right chest cavity about half full of fluid which proved to be blood.

into the pleural cavity. In reviewing the literature there were no cases found in which there was an associated hemorrhage of this extent.

Riverside Infirmary

ABSTRACT OF DISCUSSION

DR JOHN M. BARNES, Ann Arbor, Mich. This paper introduces an entity that may be confused with a manifestation of early tuberculosis. The diagnosis of idiopathic pneumothorax should be made only after one has exhausted all efforts to establish a cause for the pneumothorax. In the university health service and hospital we have had six cases, all of them in young white men. In one case fluid developed following the pneumothorax. There were no cases with blood. One of the cases was of the recurrent type and I think goes to show that this condition can occur without any definite infectious process in the lung. In this particular instance the man had four attacks within a year. He was followed both at Ann Arbor and at

Walter Reed. In neither place was there any evidence of pulmonary disorder found. In this instance, then, we are dealing with this obscure type, which is known as idiopathic. It may be due to a bleb. The only thing in his history that was suggestive as to cause was an allergic tendency. He had hay fever but no asthmatic symptoms.

DR W. K. LINT, Detroit. I myself have had the experience of going through pneumothorax. In my case, however, I believe it was due to a postoperative condition. I had a mastoid operation a few months previous to the spontaneous pneumothorax. I was walking one day, to take a street car, and had gone about half a block, when I suddenly experienced a peculiar sharp pain in my side. My respiration immediately became rapid and breathing short. Fortunately there were two of my friends with me and they helped me back to where I came from. My left lung was completely collapsed and my heart was displaced almost entirely to the right. Being a medical man I have had the good fortune of being able to check up the condition from the day of the occurrence until today. It took me two years to eliminate the fluid at the base of the left chest. I had films taken of it at intervals of about every six months. I am interested in Dr. Taft's paper because I want to find out just what is the exact cause of a spontaneous pneumothorax. Tuberculosis, they would say, but here I am still standing before you seven years after the occurrence. I have in mind two other cases. One was, I believe, due to an extreme exertion. The patient was suffering from asthma. Asthmatic patients, as a rule, do not have tuberculosis. He unfortunately died of a decompensated heart. The other case was due to trauma, and the patient kept on working and held his job.

DR R. T. WILSON, Temple, Texas. I have had the unusual experience of observing this idiopathic pneumothorax occur in both lungs in the same patient at different times. A university student about 21 years of age developed the typical stabbing pain without apparent cause, from which he recovered in about a month. Thirty-one days from the first attack he developed exactly the same type of lesion, so far as could be determined, in the other side. Every type of examination was made even by a tuberculosis specialist. The cause has not been discovered yet. At a recent examination no evidence of the condition could be found and the patient felt that he was perfectly well.

DR L. T. LEWIS, New York. Along the same line I have one case in which there was a bilateral pneumothorax of this spontaneous type, in which collapse on the left side followed within a week after collapse of the right side. There is a question in that particular case whether air may or may not have gone across the mediastinal septum. Some experimental work on dogs has shown that it is possible for a communication to exist between the two sides through the mediastinum; that is, colored fluid put in one side of the chest appears on the opposite side within a few hours. In my case, the young man who had a bilateral spontaneous pneumothorax fortunately did not have a complete collapse such as occurs in some cases, but a partial collapse, and a week later showed just about the same amount of collapse on the opposite side. He made a complete recovery and has shown no evidence of tuberculosis. The other point I wish to stress is that some patients are slow in recovering the expansion of the lung. I have one case in which expansion has not occurred after a number of years. In one case expansion occurred just about as hope had been given up, about a year afterward. In that case aspiration of air was done two or three times and the patient was directed to cause some increased pressure by blowing water from one bottle to another, and finally complete expansion occurred and he has had no signs of tuberculosis or any recurrence of collapse. I had one other case recently in which there was collapse on one side and after recovery there was collapse on the other side. The point that I think ought to be stressed particularly from the roentgenologic standpoint is that there is this type which is not associated with tuberculosis. I think it is unfortunate if that is not stressed because a patient who suffers from this condition, if it is not definitely told him, will think it resulted from some serious trouble with his lungs, particularly tuberculosis. I think that is a grave mistake. I have seen about twenty-five cases and I have seen also a number of cases complicating tuberculosis. I have seen it also occur on both sides in tuberculosis. In the twenty-five nontuberculous cases the only complication has been

a pleural hemorrhage in one or two, and the delayed expansion over some time, but in none of these cases—and some of them go back fully eighteen years—has there developed any tuberculosis. I have followed several of them with care roentgenographically for years.

DR ROBERT B. TAFT, Charleston, S. C. Another thing that I wanted to bring out is the frequency of pneumothoraces that I have seen ushering in tuberculosis. For example, a patient who seems to be absolutely healthy will develop a pneumothorax. After the lung is expanded examination discloses a definite tuberculous lesion. A good many of those cases I have seen, I dare say within the past three years' time. I have never seen mention in any textbook about the frequency of tuberculosis being ushered in by that.

THE PRESENT-DAY MANAGEMENT OF STONE IN THE KIDNEY

CHARLES PIERRE MATHÉ

SAN FRANCISCO

Stone has received more attention than any other lesion of the kidney, however, certain conservative methods are retained which often result in the destruction of the kidney harboring the stone, and certain benign operations are continued which, in spite of being popularized for their simplicity and safety, favor the recurrence of stone. This paper reviews seventy-four cases of renal calculi removed by surgical intervention or cystoscopic maneuvers. Silent, quiescent, non-obstructing calculi unaccompanied by infection were untreated and are not included. The etiologic role of congenital deformity, stasis and infection is carefully studied and correction emphasized. The pathologic effects of stone, pyelonephritis, ulcerative necrosis, renal abscess, perinephric abscess and hydronephrosis are thoughtfully considered. These pathologic processes progressively destroy the kidney and emphasize the necessity of early recognition and removal of stone. Several cases presenting the so-called nonsurgical coral-form type of stone are reported in which fragments broke off and passed into the ureter, caused obstruction, and resulted in rupture of the kidney, abscess formation or other grave complications. Nephrotomy, pyelotomy and pyelonephrotomy are selected for the different types of stone with the purpose of conserving renal tissue and minimizing recurrence.

REPORT OF CASES

CASE 1—J. S., a man aged 58, a lawyer referred by Dr. John Gallwey, entered St. Mary's Hospital Dec. 20, 1928, because of pain and swelling in the right lumbar region accompanied by nausea and vomiting and followed by chills and fever. At 55 an impacted stone was removed from the urethra following which he passed gravel and numerous stones. Five months later a larger stone was removed from the urethra. When the patient was 56 I performed a lithotripsy for bladder stone. At this time roentgenograms revealed a coral-shaped stone in both kidneys and a spindle-shaped calculus in the lower left ureter. Following meatotomy and dilation of the left ureter the stone passed into the bladder and was removed by rongeur forceps. The patient was advised to have the stones in both kidneys removed by operation but intervention was refused. From time to time fragments from the stones in the kidneys passed down the ureter and were expelled spontaneously or removed from the bladder through the operative cystoscope. Urine examination revealed masses of leukocytes and erythrocytes, albumin and myriads of colon bacilli and

staphylococci. A phenolsulphonphthalein intramuscular test resulted in the return of 15 per cent in two hours. Examination of the blood revealed hemoglobin 41 per cent, erythrocytes 3,142,000, and leukocytes 27,300, 11 mg. of creatinine was recovered in 100 cc. of blood. Roentgenograms revealed a large right kidney, obscuration of the psoas shadow and a calculus in the region of the ureteropelvic junction. The catheter could not be passed by this impacted calculus.

Jan. 21, 1928, a transfusion was made.

January 23 the kidney was attacked through a lumbar incision and when the renal loge was opened 1000 cc. of thick pus was liberated from a perinephric abscess which had caused compression on the liver and diaphragm. A firmly impacted stone measuring 2.5 by 1 cm. was removed by a pyelotomy incision. A number of cortical abscesses were found in the kidney. Because of the severity of the infection and the extreme debility of the patient, the kidney was not removed. Following this procedure the patient greatly improved but the wound continued to drain pus. He left the hospital February 21, the leukocyte count had dropped to 12,400 and he felt stronger. About two months later the infectious process present in the right kidney underwent considerable necrosis and invaded the lung. Mercurochrome-220 soluble injected into the lumbar sinus would immediately be coughed up by the patient. The renal function progressively lowered and on Christmas 1928 the patient developed influenzal pneumonia and died.

This case exemplifies the constant danger of the type of coral-shaped stone in which fragments break away and obstruct the ureter. The fragment that obstructed the ureteropelvic junction on the right side blocked drainage, causing acute backpressure in the kidney and extension of infection which had existed in the pelvis for years, into the cortex, resulting in multiple abscesses of the kidney and a huge perinephric abscess. At the time of operation, the patient's condition only permitted drainage and removal of the obstructing stone in the pelvis.

CASE 2—B. K., a woman, aged 68, a housewife, referred by Dr. J. H. D. Roger, entered St. Mary's Hospital, April 14, 1925, because of pain in the region of both kidneys, frequency of urination, impaired heart action and extreme debility. For the past few years the patient had passed a number of stones and experienced frequency, dysuria, hematuria, bilateral dull lumbar pain and the passage of foul smelling urine. Phenolsulphonphthalein 5 per cent was recovered in two hours after intramuscular injection. Blood examination revealed hemoglobin, 70 per cent; erythrocytes, 4,168,000; leukocytes 42,250. The urine contained albumin, masses of leukocytes and erythrocytes and swarms of bacteria. Roentgenograms revealed stones in both kidneys which were considerably enlarged also a stone in the region of the lower portion of the right ureter. As the patient was in a precomatose condition eliminating practically no urine immediate drainage was advised and refused. The patient developed complete suppression of urine, went into uremia and died a week later.

Necropsy revealed a left pronephrotic kidney presenting numerous abscesses. A number of stones were found in this kidney, one was tightly impacted in the ureteropelvic junction obstructing the outflow of urine. The right kidney showed acute hydronephrosis, the obstruction being a stone in the lower ureter. One may assume that if the stone had been removed from the lower right ureter when the patient was first seen the relief of obstruction might have allowed the renal function to return in the kidney presenting rather early hydronephrotic changes. Infection in the right kidney had ended in entirely destroying this organ and nothing could have been done except radical removal.

CASE 3—H. T., a man aged 45, a former middle weight prize fighter entered St. Mary's Hospital Feb. 11, 1924, complaining of pain and swelling in the region of the right kidney, the passage of gravel, hematuria, dysuria, edema of the eyelids, loss of weight and weakness. At the age of 43 a number of calculi passed from the right ureter following cystoscopic

maneuvers consisting of merotomy of the ureteral orifice and progressive dilation of the ureter with bougies. In performing the phenolsulphonphthalein test 50 per cent was recovered in two hours after intramuscular injection. A roentgenogram revealed a calculus in the left kidney pelvis and impacted stone in the right lower ureter, bilateral pyelonephritis and hydronephrosis and hydronephrosis on the right side. One-half hour after intravenous injection, 12.5 per cent phenolsulphonphthalein was recovered from the right ureter and 5 per cent from the left ureter. Operation was advised it being my purpose to remove the calculus from the left kidney in which the infection was less than in its fellow. Operation was refused and subsequent examination October 6, revealed a calculus forming in the right kidney pelvis. Bilateral merotomy and renal lavages were performed and progressive dilation of the ureters was made following which the patient passed dozens of stones from the right kidney the largest of which measured 1 cm in diameter. October 21, a piece of one of the stones (which had rapidly increased in size and number in the right kidney) passed down the ureter and completely obstructed it. The patient presented a huge swelling in the kidney region, had a high fever and was toxic. In spite of the drainage of pure pus obtained by passing two number 6 Charrière ureteral catheters beyond the obstructing stone the patient became more toxic and progressively weaker. September 26, a nephrectomy

removed at once. These might completely obstruct the ureter at any time and in kidneys presenting chronic pyelonephritis cause invasion of the cortex by the infecting organisms present, resulting in complete destruction of this organ.

ETIOLOGIC ROLE OF STASIS AND INFECTION

The etiology of stone formation is still unsolved, however, in certain individuals it is due to chemical and metabolic processes more or less influenced by the food intake. Keyser¹ was able to reproduce calculi in the kidneys of rabbits by feeding experiments. Holmes and Caplan² recently made a geographic survey of stone in the United States and attributed the high incidence of stone formation in southern Florida to the excessive intake of fruits and vegetables, the alkaline ash producing foods overwhelm the protective mechanism in the urine, resulting in the formation of stone. It is not uncommon to see calculi rapidly increase in size in patients who, in their zeal to combat acidity and prevent stone formation, overwhelm the system with mineral waters of high alkaline concentration. Numerous investigators have emphasized the role of faulty metabolism brought about by diet and climate, yet it is not in the scope of this paper to discuss them. In some instances stone formation is favored by stasis, as evidenced by finding stones in the bladder and kidneys where free drainage is obstructed by the hypertrophied prostate or by a urethral stricture. Likewise, one often finds stones in kidneys presenting congenital anomalies, such as the horseshoe kidney, ectopia, bifid pelvis and ureter, congenital hydronephrosis and hydro-ureter, in which the drainage of urine is impeded by malformation. Hunner³ has called attention to the role of the ureteral stricture in the production of stone. Burford,⁴ Ward⁵ and Pillet⁶ have emphasized the incidence of stone in ptotic kidneys. Forty per cent of the cases here reported presented stasis in the upper and lower urinary tract (table 4), and as far as I was able I corrected these obstructive lesions.

Infection also plays a role in the production of stone. There is no doubt that certain stones form around a nucleus consisting of bacteria. The bacteria cohere by and of mucinous cement material present on top of which urinary salts are readily precipitated. In others precipitation of urinary salts is due to chemical changes caused by the micro-organisms themselves. On the other hand, infection may be the result of chronic irritation due to the stone which reduces the local resistance of the kidney, making it more susceptible to invasion. After infection has set in it may cause the formation of secondary stones. The secondary role of infection in certain cases is exemplified by the prompt disappearance of inflammatory processes sometimes following the removal of stone. After the removal, pyelonephritis

Fig. 1 (case 1)—A coral shaped fragmenting stones in both kidneys in a man aged 58 accompanied by infection. B ureteropyelogram locating calculus and showing early hydronephrosis. Operation was advised and refused. Obstruction caused by a fragment lodging in the right ureteropelvic juncture resulted in an abscess of the kidney, perinephric abscess and lung fistula. Surgical removal of the calculus and drainage of the abscess were done with amelioration of symptoms. The patient died a year later of pneumonia.

was performed and a large pyonephrotic kidney containing numerous calculi, the largest 5 cm in diameter, were removed. The ureteral calculus was grasped by long forceps and removed through an opening high up in the ureter. The convalescence was somewhat stormy and the patient left the hospital three weeks later. Since that time, repeated roentgenograms have been taken of the remaining left kidney. It has greatly hypertrophied and the calculus contained in it has taken on a coral shape and has almost entirely filled the pelvis and calices and on Feb. 6, 1930, measured approximately 8 by 3 cm. This calculus is apparently of a harder nature than those that had been present in the right kidney as no pieces have broken off. There has been no obstruction of the left ureter nor any passage of small calculi. The patient has refused operation on the remaining kidney and in spite of the huge stone in his solitary kidney enjoys fair health some six years after nephrectomy for right sided calculus pyonephrosis.

This case exemplifies the importance of early surgical intervention for stone before renal insufficiency and advanced infection has set in, making the patient a poor surgical risk. It also demonstrates that stones multiple coral-shaped or otherwise, in which fragments separate and pass down the ureter, should be

(35 per cent) was treated by pelvic lavage and the administration of urinary antiseptics. In addition I acidified the urine of patients presenting alkaline stones and alkalinized the urine of patients presenting acid and cystine stones, regulated the diet based on a chemical analysis of the stone found, and limited the patient to distilled water. It was observed that recurrence was greater in kidneys in which it was impossible to relieve the infection.

Fig 2 (case 1)—Fragments detached from coral shaped stones in both kidneys either expelled spontaneously or removed through the operating cystoscope

All patients were carefully examined for all possible foci of infection in other parts of the body with specific attention to infections of the skin, tonsils, sinuses and middle ear, teeth and infected genital organs.

As far as I was able I corrected stasis and infection and, further, I deduced that recurrence noted in 20 per cent of the cases was due either to improper surgical technic favoring the leaving of fragments or to an inherent predisposition of the patient to form stone. Although all foci of infection had been removed and renal infection and stasis relieved, the role of faulty metabolism is exemplified by the fact that calculus occurred in the opposite kidney (9 per cent of cases).

PATHOLOGIC EFFECTS OF STONE

It matters little whether infection is directly the cause of stone formation or whether the stone is responsible for infection. If the stone is not removed it may lead to infection of the kidney and by irritation and pressure cause ulcerative necrosis or abscess formation. When it occludes the pelvis or a calyx it may even cause invasion of the parenchyma by infecting organisms resulting in a single abscess or suppurative nephritis more or less destructive to the kidney. If unchecked, the pathologic process extends to the perinephric tissues by way of the lymphatics or by direct invasion giving rise to perinephritis, sclerotic peripyelitis, paranephritis or perinephric abscess. If unrelieved, a perinephric abscess may perforate the diaphragm and invade the lung as was observed in one of my cases in which a lung fistula resulted. The stone or its accompanying infection can act as a focus of stone formation and hematogenous infection of the opposite kidney. The occluding stone often results in hydronephrosis, so commonly observed with thinning of the sac, or less frequently to sclerosis of the pelvis with thickening of the wall and perirenal fat. Stone may also cause spontaneous rupture of the pelvis, as was observed in two of my cases, and renders the kidneys more susceptible to traumatic rupture by reason of the thinning of the pelvic wall due to hydronephrosis.

The constant irritation of the calculus in the kidney sometimes leads to tumor formation. When accom-

panied by streptococcal pyelonephritis it is sometimes a factor in causing invasion of the blood stream, producing septicemia, endocarditis and death. This was observed in two cases presenting this type of infection, in which the calculi were not removed from the kidney.

TREATMENT

In treating kidney stone, the greatest precautions should be taken to conserve renal tissue and to prevent recurrence. These consist of the employment of the proper operative procedure, which is determined by the size, shape and position of the stone and after removal the application of all prophylactic measures against future stone formation. Stones measuring less than 5 mm in diameter can be encouraged to pass into the ureter and bladder by cystoscopic maneuvers. These consist of enlarging the constricted ureteral orifice by meatotomy, progressive dilation of the ureter with catheters and bougies, and the employment of succussion, recently advocated by Bransford Lewis.⁸ Ten per cent of the cases presenting stone, reported in this series, passed into the bladder following these manipulations and were either voided spontaneously or removed with rongeur forceps through the operating cystoscope. When the stone has a greater diameter than 6 mm one should resort to surgical intervention, employing pyelotomy, nephrotomy, pyelonephrotomy or nephrectomy. Operation is particularly contraindicated in the aged. Quiescent, silent, nonobstructing stones in kidneys presenting no infection were left alone. The disintegration of a cystine stone by pelvic lavage with alkaline solutions, recently reported by Crowell,⁹ offers great possibilities of dissolving stones in situ employing either acids or alkalis, based on chemical analysis of the urine and of fragments that might have been passed.

Fig 3—The end result of untreated renal calculi is exemplified by this kidney removed from a woman aged 41 presenting calculous pyelonephrosis in which the organ was entirely destroyed by urea decomposing organisms.

Pyelotomy—This operation has become popular because it is benign, is safe, offers an easy approach, sacrifices little renal tissue, and is unlikely to be followed by hemorrhage. It is ideal for smooth stones situated in any portion of the pelvis and particularly for those which obstruct the ureteropelvic outlet.

⁸ Lewis, Bransford. Stones in the Kidney Pelvis. A Nonoperative Method of Removal with the Aid of the Cystoscope. *J. A. M. A.* 85: 1056 (Oct. 3) 1923.

⁹ Crowell, A. J. Cystine Nephrolithiasis. *J. Urol.* 11: 545 (June) 1924.

Because of its facility, pyelotomy is also applied to pelvic stones, coral-shaped and otherwise which contain single or multiple branches extending into the calices of the kidney. Some surgeons crush these stones and extract or wash away the smaller fragments. Stones situated in the lower, middle or upper calyx can also be located and removed through the pelvic incision. Unfortunately, in performing pyelotomy and particularly when the stone is crushed, one is likely to leave small fragments which will not even show in making a fluoroscopic examination or in taking roentgenograms at the time of the operation, as suggested by Braasch and Carman¹⁰ or by Quinby,¹¹ nor be detected by careful palpation. These fragments are sometimes firmly attached to the stone bed and although infinitesimal in size act as nuclei for future stone formation. In the twenty-two kidneys from which stones were removed by pyelotomy, five recurred (22 per cent), two in the lower

tissue, one should attempt to remove stones by multiple nephrotomy incisions when possible rather than by laying the kidney wide open by one huge incision. Although this operation is more dangerous than pyelotomy, it should be employed when the latter is too difficult.¹² It has the advantage of being followed by fewer recurrences.¹³

Pyelonephrotomy—The combination of pyelotomy and nephrotomy, although not in general use, is ideal for the removal of a calculus situated in a calyx or pelvic

Fig. 4—Pyelonephrotomy for stone. An incision is made in the pelvis through which the index finger is inserted to support the stone from below. Single or multiple nephrotomy incisions are made with a silver wire after the stones have been located by needling. Prior to operation a catheter is placed in the ureter in order to irrigate the pelvis and to prevent fragments from passing into the ureter.

calyx, two in kidneys presenting a large branched stone that had extended into the calices, and one in the middle calyx.

Nephrolithotomy—This type of intervention is indicated when one encounters an intrarenal type of pelvis. It is more likely to be accompanied by hemorrhage at the time of operation or secondary hemorrhage occurring usually from ten to fourteen days later. It also has the disadvantage of sacrificing a certain amount of renal tissue and gives a poorer approach for removing that portion of the stone extending into the pelvis. The employment of the silver wire which pushes aside the larger ramifications of the renal vessels and severs only the smaller terminal branches reduces the amount of renal tissue destroyed. In order to conserve kidney

stones whose branches extend into one or more calices. It permits one to remove the smaller ramifications through single or multiple nephrotomy incisions and assures extraction of the portion of the stone located in the pelvis. An incision is made in the posterior wall of the pelvis, the finger is inserted, and the stone is palpated and kept in place by firm gentle pressure. At the same time it is located from without by the aid of a small groove director or blunt needle,¹⁴ which acts

At the time of operation faulty drainage should be corrected; the ptotic kidney should be anchored to the last rib by nephropexy. When not too large anomalous vessels obstructing the ureteropelvic junction should be resected and anastomosis and other constrictions of the ureteropelvic outlet corrected by the proper plastic operation. Coincident abscesses should be drained and in certain cases of advanced infection a

rubber drain tube is inserted into the pelvis and brought out through the parenchyma of the kidney for the purpose of lavage. During the operation, fragments are likely to pass down the ureter and cause subsequent trouble. This is prevented by passing a large ureteral catheter into the pelvis prior to intervention. It facilitates location of the upper portion of the ureter, allows one to make a constant lavage of the pelvis with a mild antiseptic solution and to wash away small fragments. It assures ureteral drainage after the operation.

It is today acknowledged that large coral-shaped, silent, nonobstructing stones should be left alone. In certain coral-shaped stones, however, fragments break off, pass into the pelvis and ureter and may be arrested at the ureteropelvic junction or along the ureter. The resulting obstruction leads to backpressure and in the event of chronic pyelonephritis may cause invasion of

Fig. 5—A stone is either pushed away from its bed or removed with forceps. Counterpressure by the finger assures more complete removal of the stone and less likelihood of leaving fragments.

the cortex, ending in suppurative nephritis which partially or completely destroys the kidney. I have observed this type of coral-shaped stone in five patients. In one the kidney was completely destroyed and the patient's life was saved by prompt nephrectomy. In the second case, impaction of the stone caused rupture of the kidney necessitating immediate intervention. In the third, a fragment obstructing the ureteropelvic junction was responsible for the formation of multiple cortical abscesses accompanied by a huge perinephric abscess. In the fourth, the coral-shaped stone occurred in a patient possessing a solitary kidney and the destruction of this organ by multiple abscesses resulted in death. In the fifth, a fragment obstructed the ureteropelvic junction, causing complete blockage. The other kidney had been destroyed by a pyonephrotic process and as the patient refused operation she rapidly went into uremia and died. If a patient presenting coral-shaped stone of one or both kidneys gives a history of passing fragments operative intervention should be instituted at once. The early removal of this type of stone

assures elimination of urine and conservation of renal tissue. In addition, the patient is surely a better risk than at a later date, at which time advanced infection or renal insufficiency will have taken place. If the stone recurs, it can again be removed. I successfully performed three consecutive operations for this type of recurring coral-shaped stone with relatively little damage to the functioning power of the kidney.

OPERATION ON SOLITARY KIDNEY

In removing stones from the solitary kidney due to congenital deformity, or disease, or surgical removal of its fellow, drainage of the urine from the kidney must be assured at all times and the technic exacting. A wider incision assuring good exposure should be made, sacrificing the twelfth rib when necessary, extreme gentleness should be employed in handling the kidney, and blood vessels should not be sacrificed. The pyelotomy incision should not be sutured in order to assure good drainage of urine. Decapsulation should be made to avoid postoperative congestion. Partial

Fig. 6—After the nephrotomy incision has been closed by mattress sutures partial decapsulation is performed in order to minimize post operative congestion. The capsule is separated for a slight distance only and allowed to remain on the convex surface. This facilitates subsequent operative approach of the kidney. The pyelotomy incision is not sutured in solitary kidney.

decapsulation is performed in such a manner as to assure the minimum amount of kidney surface adhering to the surrounding structures and facilitates surgical approach if it becomes necessary to operate on the kidney at a future date. This is accomplished by incising the capsule longitudinally, bluntly stripping it from the kidney with the finger for a slight distance only, and replacing the capsule on the convex surface of the kidney (fig. 5).

Nephrectomy—In individuals prone to stone formation, early nephrectomy for destructive calculous pyonephrosis removes the focus of infection, which is often the cause of subsequent infection and stone formation in the opposite kidney.¹⁵ It is realized that the kidney has a remarkable regenerative power and it is not sacrificed when there is reason to believe that

the function might return after the removal of the obstructing calculus. When multiple abscesses are encountered and when the kidney is nothing more than a sac of pus or a bag of stones, it should be removed. It is often hard to measure the amount of destruction present and to ascertain the recuperative power of the kidney. Nephrectomy is particularly indicated when there is advanced unilateral infection with urea decomposing organisms.¹⁶ In cases presenting coincidental calculi of the lower ureter, a complete ureteronephrectomy should be performed. These calculi prevent atrophy of the ureter, cause attacks of pain, and in many instances are responsible for persistence of infection in the bladder, which in turn might extend to and involve the remaining kidney. In two cases in which the kidney had been previously removed by other surgeons, it was found necessary to remove the lower ureter containing stones because of persistent pain and cystitis.

After-Care—A roentgenogram should be made before the patient leaves the hospital to assure oneself that all fragments have been removed. The patient sometimes passes fragments following the operation. A routine roentgenogram of the entire urinary tract should be made every three to six months and the urine carefully analyzed for pus and blood, the presence of which points to infection with or without stone. The finding of macroscopic or microscopic blood usually indicates recurrence of stone.

SUMMARY

1 The modern management of kidney stone includes many prophylactic measures, viz, early nephrectomy for destructive calculous pyonephrosis which might act as a focus for stone formation in its healthy fellow, the clearing up of foci in other parts of the body, the elimination of predisposing lesions consisting of stasis in the upper and lower urinary tract, the eradication of renal infection, and the correction of faulty metabolism with a diet based on a chemical analysis of the recovered stone.

2 Obstructive stones cause backpressure, resulting in certain pathologic lesions, viz, hydronephrosis, suppurative nephritis, abscess formation, perinephric abscess and spontaneous rupture of the kidney. Non-obstructive stones are a source of continual irritation to the kidney, lowering its resistance and making it more susceptible to tumor formation and to infection. Early removal of nonobstructive stones as well as the obstructive type conserves renal tissue and lengthens life.

3 The so-called nonsurgical, coral-shaped, silent, nonobstructing stone in which fragments break off, pass into the pelvis and ureter threatening obstruction, should be removed at once.

4 Recurrence of stone occurred in 20 per cent of the seventy-four cases treated. As all predisposing lesions such as stasis, renal infection and foci of infection elsewhere were systematically corrected, it might be deduced that recurrence was due to faulty metabolism or to the leaving of fragments at the time of operation. Recurrence after operation (19.7 per cent) can be further reduced by the employment of x-rays at the time of the intervention and by the intelligent selection of the proper type of operation based on the position and character of the stone. Nephropylotomy assures a more thorough removal of branched pelvic stones and stones in the calyces.

ABSTRACT OF DISCUSSION

DR A H PLACOCK, Seattle The study of renal calculus opens up at once an interesting question, for every stone is a problem by itself. I do not think that any rule can be laid down from experience that will apply to all cases. However, there are certain particular symptoms in these cases and there are certain broad considerations one could follow that are of great assistance. We are not infrequently called to see these patients and to give advice, and I think our advice should be a matter of judgment and experience. We should be influenced first of all by the size of the stone. I think we all realize that the small stone frequently will pass on into the bladder and be expelled in the natural way. Stones over 1 cm., in my experience, will not do this but the smaller stones will often pass on, perhaps with some manipulation of the ureter, and be voided through natural channels, thus offsetting a serious operation. On the other hand, I have seen some serious complications following the too frequent use of the transvesical manipulation of the ureter in an attempt to dislodge a stone. Even when the stone is finally passed, the infection resulting from manipulation has persisted for months in some instances. I think that manipulation of stones in the ureter is not advisable and believe that they should be removed by surgery if they show no tendency to pass on. The indications for surgery in my experience have been, first of all, infection. These cases which have become infected will not clear up and the earlier the stones are removed the better. The second thing is hematuria. This is often quite severe, especially in the polycystic kidney. Another thing is tenderness and pain, continuous in nature. Often these patients will have an attack of renal colic, recover from it and not have another for six months or a year. On the other hand, some patients will have repeated attacks of pain occurring at short intervals, and I do not think that these patients should be worn out by repeated attacks of colic without some surgical relief. Another indication for surgery, to my mind, is impaired unilateral function, proved by pyelogram and chemical tests showing that destruction of the kidney is going on. In the contraindications, I think that first of all comes the silent stone. I do not mean the type that Dr Mathe mentioned for that was not silent, but the type with which there are practically no symptoms and no evidence of urinary infection and the stone that is found through a general examination.

DR WILLIAM F BRAESCH, Rochester, Minn. The silent renal stone is one of the most interesting conditions to be considered. It is often quite a problem to decide whether or not to operate on a stone that is causing no symptoms. The more experience I have the more am I inclined to advise operation in every case, unless there is some definite reason against it. Because of age coincident complication, the possibility of spontaneous passage or because the stone is too large to attempt removal I might not wish to advise operation. It is usually advisable in such cases to keep the patient under observation and watch the increase in the size of the stone by repeated roentgen examinations. These stones may be silent so far as subjective symptoms are concerned but they are never silent in their injurious effect on renal tissue and usually cause destruction of the kidney. I was much interested in the various etiologic factors that Dr Mathe pointed out, and particularly in the large percentage of cases in which he found ureteral stricture to be an apparent cause. It is quite as difficult to say whether a stricture found at operation is primary or secondary as it is to determine its presence clinically. Renal or ureteral stone is so often found without any evidence whatever of stricture that it can hardly be a common etiologic factor. Furthermore, when one considers that over 90 per cent of the patients operated on for stone in the ureter or kidney did not have a recurrence and thus in spite of no treatment for a supposed stricture one must infer that stricture cannot be of much etiologic importance. Primary renal infection is not a frequent cause of lithiasis. Chronic pyelonephritis is of common occurrence but is only occasionally complicated by secondary stone. When stone does occur with primary chronic pyelonephritis it is usually small and of little clinical importance and surgical treatment is usually not indicated. Should however the stone cause pain or should there be an increase in size and infection it would be advisable to remove it. True pyonephrosis is not a common finding with renal stone although diffuse pyelonephritis is often observed.

It would be reasonable to assume that the pyonephrosis is the result rather than the cause. Infected hydronephrosis, which is often called pyonephrosis, is observed more frequently and may be either primary or secondary. When the hydronephrosis is large, say from 150 to 200 cc, it is usually primary and the stone is of secondary formation. Renal ptosis has been regarded by some observers as a frequent cause of stone. Considering the many cases of ptosis that are seen without lithiasis, one might question whether ptosis is ever an etiologic factor. I have always regarded ptosis as a coincident finding, rather than as a primary factor.

DR FREDERICK T LAU, New York. The story of urinary calculi is so broad, so interesting and so well understood that I would like to mention just one feature of Dr Mathe's paper that I greatly enjoyed—the subject of recurrence. I think that in the light of present day knowledge there are too many recurrences. I think that if one takes into consideration the points of stasis, infection and the chemical composition of the stone there will be fewer recurrences. No one will dispute the fact that stasis is the cause of stone primarily, and it is the cause of recurrence. Stasis in the course of infection causes an excess precipitation of salts in the urine. It is known, too, that the majority of stones that recur are of alkaline rather than of acid composition, and if one analyzes the chemical composition of each stone removed at operation and governs the chemical reaction of the urine according to the result of the chemical reaction of the stone, one discourages in that way the possibility of recurrence. If the stone is acid the urine should be kept alkaline, and if it is alkaline the urine should be kept acid. I had the privilege of reporting a series of cases six years ago in Chicago. The statistics in New York are about the same now as they were then. I spoke of one case at that time which I wish to mention now to bring out the points I wish to emphasize regarding recurrence. This patient prior to being seen by me, had had four operations. After she came under my observation she had three operations for continued recurrences of calculi, the earliest being three months and the last three years. When I reported her case in Chicago, in 1924, she had had the last one, in January of that year, and I am happy to report now that there has been no return of calculi since then. Her urine is alkaline, her stone is acid. She carries litmus paper with her and tests her urine regularly. At one time she got a little acidosis but has learned to be on guard. I am glad Dr Mathe reported so few nephrectomies. I think that physicians are learning to be more conservative and not to sacrifice a kidney unnecessarily.

DR ROBERT H HERBST, Chicago. I would like to emphasize the value of renal resection in the treatment of stone in the kidney. This procedure is particularly useful in polycystic stones that have produced cavities or dilatation of one or more calices also when such stones have produced a localized infection. In these cases the incidence of recurrence is high following simple removal while resection leaves a healthy functioning segment with little or no danger of recurrence. The deferred popularity of this method of treatment is due to the unwarranted fear of postoperative hemorrhage and leakage of urine. I recently carried out a study on dogs resecting a V shaped segment of the kidney. In practically every instance in which the capsule was first stripped back and then drawn over the cut end followed by the introduction of mattress sutures postoperative hemorrhage did not occur. The puckered capsule hung under the sutures is of undoubted value in the control of bleeding. Leakage will not occur from a pelvis that is draining normally. I opened a calyx or the main pelvis in all these experiments and never saw any leakage, in many I did not even suture the lining of the pelvis. Another point is the use of the indwelling ureteral catheter in the preoperative treatment of calculous pyonephrosis. A fair number of these very sick patients can be greatly improved by such drainage and an infected case converted into a fairly clean one thereby greatly reducing operative risk and at times saving a kidney that might require removal without such preoperative drainage.

DR B S BARRINGER, New York. I wish to congratulate Dr Mathe on his able paper and to say one word about the value of the roentgenogram on the table of the kidney from which a physician thinks he has removed all the stones. I think many have not done that for they think it a difficult procedure.

They can take a small x-ray film and wrap it up in a towel. It is valuable because it checks up whether all the stones have been removed or not. I think that this procedure makes one more careful, more accurate and more delicate in removing these multiple stones. I do not do it as a routine, but I do it in those cases in which I expect trouble, and I think that it has a great advantage over the fluoroscopic method, in that it is more simple and one has a permanent record of the case for one's files. It is not difficult with a small portable x-ray machine.

DR WILLIAM E. KEANE, Detroit. I think the use of the Cault scissor incisor with the bipolar current may be an advance in dislodging some of the stones that are stuck just inside the ureteral orifice. During the past year I have been successful with this method in assisting stones to pass in two such cases in which attempts by all other methods had failed. The platinum blade sears a slit in the ureteral orifice and there is no bleeding to worry about. I think that there are cases in which this method is of decided value and it can be used to advantage when indicated.

DR ARTHUR L. CHUTE, Boston. I wish to offer a word of protest about watching urinary stones for too long a time. I think it should be concluded that a stone in a kidney should not be allowed to remain indefinitely. If it will remove itself in a reasonable time, well and good; but if not it should be removed. I do not mean that all small stones should be removed the moment they are recognized. I think, in fact, that they should not. The very small stones, 1 or 2 mm in diameter, will almost certainly be passed and that opportunity should be given, but when there is a stone of any real size it is another story. The mere fact that it is known that in about 20 to 25 per cent of stone cases there will sooner or later be a stone in the other kidney should cause one to go ahead and remove a renal stone of any size, if possible before the kidney becomes infected. The fact that this tendency to formation of stones is something more than a local condition should result in their removal if they are not passed within a reasonable time. There seems, for some reason, to be a great fear of opening a kidney through its cortex for the removal of a stone. That, however, seems to me to be the logical route to follow in the removal of large stones in the calices and in the case of stone-bearing kidneys that are more or less dilated. In cases of this sort I think the logical thing to do is to make a sufficient incision through the kidney cortex, remove the stone and fix in a drainage tube. I do not mean that one should operate for a very small stone in a kidney or for one that is coming down to the ureter with reasonably free drainage. I have on a few occasions tried to remove very small renal stones but have found that this is not advisable since I have so injured one or two kidneys by a fruitless search for a small renal stone that I have had to remove them. However, the leaving of larger renal stones in the face of the fact that they are almost sure to destroy the kidney in time, and that stones will appear on the other side in one case in every four or five, is a doubtful procedure.

DR HERMAN L. KRETSCHMER, Chicago. It has been assumed for a long time that stasis and infection play a role not only with the formation of stone but also in connection with recurrences. Most physicians advise pyelotomies when this operation can be done, and also resections of the lower pole when there are evidences of dilatation and stasis, and regardless of these precautions, many of these patients go merrily on and have their recurrences. I was interested in hearing Dr. Braasch say that they have had more recurrences in cases in which pyelotomies were done. I have made it a rule to clear up the infection following the removal of the stone by means of pelvic lavage with silver nitrate, and yet in spite of these various procedures, some of the patients continue to have their recurrences. The problem of recurrences in kidney stone surgery is a big one deserving much careful study and much thought. One point that has not been emphasized in this discussion is the possible role that the kidney cell itself may play. I believe that there are some disturbances of metabolism or function in the kidney cell proper and that this is a factor in a certain number of instances in resulting recurrences.

DR. CHARLES P. MATHE, San Francisco. Dr. Edmond Papin has asked me to give his discussion. He recently saw a patient

whose case emphasizes the necessity of a thorough urologic examination in all patients presenting persistent pyuria. The patient had the clinical signs and symptoms of unilateral renal tuberculosis. In making the routine roentgenogram a silent stone was discovered in the opposite, uninfected kidney. Before removing the tuberculous kidney he removed the stone from its fellow by pyelotomy, thereby assuring free drainage of urine after the operation. In operating on silent stones, I feel that one should be guided by the same sound judgment that one employs in operating on kidneys in general. Operation is particularly contraindicated in those presenting advanced bilateral stone formation when there is severe infection and in the aged. In regard to cystoscopic maneuvers made in order to encourage stones to pass, I agree that it is unwise to expect a stone measuring 1 cm to pass through the ureter, in which the diameter rarely exceeds 0.5 cm. Every stone measuring more than 0.6 cm should be removed by operation. Heminephrectomy has not been sufficiently emphasized. After witnessing the beautiful demonstration of partial resection of the kidney for stone with infection performed by Professors Papin and von Lichtenberg before the recent meeting of the American Urological Association in New York, I am further convinced of the value of this operation. Dr. W. E. Stevens of San Francisco has also successfully used this procedure. This operation assures removal of the stone as well as of the diseased portion of the kidney in which as Dr. Kretschmer has pointed out, the renal cells are often at fault thereby playing a role in the formation and recurrence of stone. I fully agree that preoperative care is very important. One attempts to lower the amount of infection by all the modern methods at one's command, including continual ureteral catheter drainage and repeated renal lavage. Recurrence should be combated energetically. I recall a patient in whom a stone recurred after three successive nephrolithotomies. Because of this a minute examination of the urine was made and its reaction changed by placing the patient on an acid. The stone has not recurred.

RADIATION THERAPY IN CANCER OF THE MOUTH

WITH ESPECIAL REFERENCE TO THE USE OF
PURE GAMMA RAYS*

G. E. PFAHLER, M.D., Sc.D.

AND

J. H. VASTINE, M.D.

PHILADELPHIA

The fact that the British government has recently purchased 20 Gm of radium, that New York State is to add 4 Gm to its present holdings and that many institutions devoted entirely to the treatment of cancer, such as the Radium Institute in Paris, the Radiumhemmet in Stockholm and the Memorial Hospital in New York depend in great part on radium for their results, indicates definitely the recognition of the value of irradiation in the treatment of cancer. The greatest fields of usefulness, however, have been in cancer of the skin, the mouth or the uterus.

We believe that most cancers of the mouth can be prevented by eliminating all forms of irritation, such as come from tobacco, jagged or sharp edged teeth, infected gums, badly fitting plates or foreign bodies, and by eliminating syphilis.

The best time to cure cancer, even by irradiation, is in its earliest stages. Accurate and early diagnosis is therefore a most important factor. Cancer of the

* Because of lack of space this article is abbreviated in THE JOURNAL by the omission of an illustration. The complete article appears in the authors' reprints.

* Read before the Section on Radiology at the Eighty First Annual Session of the American Medical Association, Detroit, June 25, 1930 and associated with an exhibit of casts, drawings, materials and lantern slides in the Scientific Exhibit; therefore few illustrations of the technique are being published.

mouth nearly always gives some symptom that should attract the patient's attention early. Any lesion in the mouth can be easily seen and palpated. Therefore, if the patient and the physician are alert, there is no good excuse for not diagnosing cancer in its earliest stages. Better still, the lesions preceding cancer should be diagnosed and, if they are properly treated, many cancers

warty and ulcerated. At this later stage it is usually cancerous. This leukoplakia is most commonly found in those who use tobacco excessively, either smoking or chewing, and it occurs especially when there is some associated local irritation from a jagged or sharp edged tooth or badly fitting plate. This preliminary condition can be corrected by eliminating tobacco and the irritation, using an alkaline mouth wash, and if necessary by skilful destruction by electrocoagulation. If there is thought of cancer, a section should be removed for microscopic examination and in addition the area should be treated locally within radium at once, while waiting for the report. We have never seen any ill effects from the removal of a specimen, provided the area is treated immediately before or immediately after the biopsy. The danger from a biopsy results from the delay in treatment, and the growth is increased as a result of the increased blood supply that follows nature's method of repair.

At times an irritation ulcer is present, resulting from some jagged or sharp edged tooth or badly fitting plate. These ulcers, if found early, may disappear after the simple removal of the irritation, or they may become indurated and definitely malignant. One must think of cancer when there is no tendency to heal after two weeks.

A papilloma may develop from one cause or another, which in turn may be subjected to traumatism and then become malignant. For this reason we believe in the prompt destruction by electrocoagulation of any such lesion as soon as it is demonstrated, doing a biopsy if there is thought of a malignant condition.

Local induration of the tongue must be viewed with suspicion and kept under close observation. Malignant disease beginning in this manner is always the most difficult to diagnose, and the greatest clinical experience should be utilized.

Cancer of the lip, in which cures are obtained in practically all cases if treated at the beginning, will not be discussed in this paper.

THE USE OF PURE GAMMA RADIATION

We have obtained some rather brilliant results in the past with electrocoagulation, insertion of radium needles, and combinations of these with surgery, but for the most part the ultimate results have been disappointing, and even those patients who were cured went through much suffering and distress. Acting on the biologic principles of irradiation laid down by Regaud, we increased our filtration and prolonged the application of radiation. The end-results were so much superior to the former results obtained that we have adopted this method as a routine. We presented the matter after invitation of the British Empire Cancer Commission before the International Conference on Cancer held in London in July, 1928,¹ and discussed it further before the American Radium Society in 1929.² Later, while visiting the Radiumhemmet in Stockholm and the Curie Institute in Paris, we found that practically the same methods were being used and with similar results.

This improved technique is based on two fundamental principles laid down by Regaud. He recommends that

Fig 1 (case 1)—F. P. P., a man aged 43 referred by Dr. S. Irwin Darnall, Sept. 26, 1927, with recurrent carcinoma involving 2 1/2 inches of the right lower jaw and producing a mass of tumor about the size of half a hen's egg and associated with destruction of the jaw bone below the inferior dental canal. A, before treatment; B, June 9, 1928, showing area completely healed; C, Oct. 13, 1928, showing that the results have been accomplished without any damage to the skin.

can be prevented. We believe that most cancers of the mouth evolve from some preceding, slowly developing lesion.

There may be white patches or a general whiteness of the mucous membrane, which is almost transparent at the beginning and later this may become thickened,

irradiation be prolonged so as to destroy all the cancer cells in the process of division, and says, "It is useless to expect to kill all the cells of a squamous cell cancer, it is sufficient to kill the mother cells, the others, which form practically the whole mass, disappear gradually by transformation and resorption." His idea, therefore, is that a moderate amount of irradiation continued over a considerable time is better than a great amount of irradiation given in a short time. His second principle is indicated by the following "As the radiation becomes more penetrating, the diffuse necrotizing effects diminish, then practically disappear, and finally only the selective effects remain, which are manifested in the most radiosensitive cells, which are the cancer cells

tion effects up to the limit of normal tissue tolerance for a considerable time. Regaud says

When radium punctures was first begun it was thought that it might become the method of choice in the majority of cancers. Instead its use has been greatly restricted so that at present it is employed only for cancer of the tongue and a few times for thick exuberant cancers of the skin.

Since using the method here described, we have had much more satisfactory results, with almost no damage to the normal tissues. We believe that by eliminating the fear of operation and the fear of mutilation one will do much to prevent the delay that now occurs in the proper treatment of cancer of the mouth.

GENERAL TECHNIC

For general surface applications, as a rule, we use the beeswax and hard wood powder compound that was developed at the Radium Institute in Paris by Esquerra, Monod and Richard.⁶ We use 1 pound of beeswax, 1 pound of paraffin and 2 ounces of hard wood powder. As a rule, from 1 to 2 cm in thickness is sufficient, and the additional thickness and distance are obtained by the use of felt. At the Paris Institute, blocks of cork are used to add thickness. The wax compound is melted and molded into plaques 15 by 33 cm and 1 or 2 cm in thickness. For use, this wax is softened in hot water and then molded to the part to be treated and fixed by dipping in cold water. It is then built up to the desired thickness of from 4 to 5 cm by means of felt. The outer surface is then covered with adhesive plaster, having the sticky surface outward. The radium units are then placed as desired and held in place by strips of adhesive plaster. The radium is distributed over the surface in 5 or 10 mg units according to the location of the disease and the effects to be produced. We usually employ from 100 to 300 mg on these packs. The adhesive plaster is softened and removed, when desired, by means of carbon tetrachloride.

These wax molds are applied externally and permit the preparation of the radium packs for treatment of cases of the mouth with the least amount of exposure of the technician, they can be quickly applied and thus reduce the exposure of the radiologist, and they are molded to the part, so that they will remain in place, and the radium will always be at a constant distance. The packs are held in place by bandages and adhesive plaster. The packs have the disadvantage of being rather heavy. The weight can be reduced by using gold or platinum for filtration instead of brass or lead, but that also increases the cost. Whenever it is practical we use felt alone and omit the wax, which also reduces the weight, but it is applicable only when the surface of application is rather flat and the area over which the radium is to be applied is small.

Generally, we apply the radium to both sides because of the great tendency for cancer of the mouth (even cancer of the cheek) to spread to the opposite side. The chief object of these packs is to prevent or eliminate the metastases and in our hands they have been effectual. We usually use from 150 to 200 mg to the affected side and from 50 to 100 to the opposite side, arranging it so that on the affected side we center on the most likely region of lymphatic extension.

By means of these packs, we commonly use from 20,000 to 50,000 milligram hours of radium element irradiation.

Fig. 2 (case 1)—Condition of jaw bone. A Sept. 26 1927 showing involvement. B April 6 1929 showing healthy condition of the bone. The patient has remained well to date. It had been thought previously that when the bone was invaded the patient could not recover by irradiation.

in the process of division." So far as we are aware, we were the first to carry these two principles to such a high degree, namely, the filtration of rays from the radium through the equivalent of 3 or 4 mm of lead and the prolongation of the effect during three or four weeks' time. In this way one also combines the principles of the "saturation method" by keeping the radium

diation in surface application, externally, at a distance of 4 cm. We have found that under these circumstances we can give as our limit about 24,000 mg. hours within two weeks and usually 36,000 within three or four weeks. In this way we obtain and keep a deep erythema of the skin and this is followed by desquamation of the epidermis. We must, of course, use more radiation in an advanced case than in an early case. This is a matter chiefly of clinical judgment. We aim to give the radium treatment which we can plan in advance during a period of from three to four weeks. During this period we give from 1,000 to 3,000 mg. hours on the inside of the mouth and we interpose these local treatments between the periods when the radium packs are being used.

For applications inside the mouth, one must improvise appliances continually to suit the individual case, so arranged that they will direct the radiation to the best advantage into the diseased tissues and at the same time protect the healthy tissue. Ready made equipment will not meet the variable needs. For this purpose, we use curved metal tubes to hold capsules against the pharynx, tonsil and posterior surface of the tongue. At times one can use a tonsil clamp. Lead of one-eighth inch thickness can be cut and bent into the form of clasps, as recommended by Grier,⁷ to hold the radium in place, or dental compound may be used to make molds, as recommended by Edling.⁸ Skill in the making of the applications is an important factor in the ultimate success. In all instances, the radium capsules and metal holders used inside the mouth must be protected by rubber or damage will be done by the secondary radiation from the metal. For this purpose we have found vulcanizing rubber to be the most practical and the most easily managed. We have been using this for about twelve years. We do not know of its having been mentioned previously.

Cancer of the mouth cannot be treated by rule. Each case is an individual problem. In the scientific exhibit we have shown examples of our methods and of the results obtained, but no two cases are alike and no two are treated alike.

Our best results have been obtained by surface applications on the inside as well as on the outside, but when the disease is of long duration or when there have been previous treatments and scar tissue formation, the induration does not always disappear, and one cannot be satisfied until it has disappeared. After preliminary irradiation we sometimes remove these areas by electrothermic methods, or we insert radium needles, or it may be well to do a local excision.

When we use radium needles, we prefer iridioplatinum of the filter value equivalent to 1 mm. of lead. We at times use 10 mg. needles or 5 mg. needles with half this filter value. These are left in place from six to twelve hours, but when steel needles (0.4 mm. walls) are used they cannot be left in place more than from three to five hours unless a local necrosis is desired. With needles and with electrocoagulation we sometimes get troublesome sloughing. We make it a rule to apply surface applications at least by packs, within a week after the needling because of the associated congestion which follows needling and which may favor growth by increasing the blood supply to any cancer cells that may have been left living.

RESULTS OF PURE GAMMA RADIATION

As a result of the application of radium element applied locally in the mouth, with a filtration of at least 1 mm. of platinum and of 2 mm. when the space will permit (which eliminates about 14 per cent of the softer gamma rays) we may expect a disappearance of the local growth in nearly all instances. This effect has the following requirements:

- 1 The lesion must be attacked from as many angles as possible and at a distance of from 3 to 6 mm.

- 2 The effect must be continued over a period of about three weeks.

- 3 It is carried to the extent of making the local mucous membrane white, and at times to desquamate.

- 4 The normal tissue must be protected as much as possible by 3 mm. of lead covered with rubber.

Fig. 3 (case 2).—H. W., a man aged 64, referred by Dr. J. Fred Wagner, Nov. 24, 1924, with carcinoma involving the entire right upper alveolar process with destruction of the floor of the antrum. *A*, before treatment; *B*, showing the lesion entirely healed by irradiation, May 15, 1925. The patient is still well.

5 When there has been previous treatment and much fibrous or scar tissue, the area must be excised (after preliminary irradiation) or radium needles must be inserted. Such hard or fibrous lesions never give as satisfactory results as a recent or untreated case.

Epithelioma developing on the basis of leukoplakia may have to be destroyed by electrocoagulation. In leukoplakia, other lesions are likely to develop at some other part of the mouth long after the original lesion has been well. Such lesions have all the appearances of new lesions but because of previous irradiation are more radio resistant, therefore a case of leukoplakia must be kept under observation and in all cancers of the mouth tobacco in any form should be prohibited.

⁷ Crier, C. W. The Treatment of Malignant Diseases in the Mouth. *Am. J. Roentgenol.* 12: 347-352 (Oct.) 1924.
⁸ Edling, I. On Plastic Means of Application in Radium Therapy. *Acta Radiologica* 1: 60-2: 219, 1921.

In cancers of the mouth treated in this manner there is never any mutilation or destruction of the tissues other than what was destroyed by the cancer.

Dryness of the mouth is a common result of the heavy external irradiation in some of the cases, but this symptom usually disappears after several months, as the salivary glands recover.

We have treated by this method during the past six years 111 cases of intra-oral cancer. This analysis includes only intra-oral cases treated since May 1, 1924. It does not include cancer of the lip or those intra-oral cases treated by other methods before or during the early development of this technique. During this time our technique has been gradually developed and therefore in the earlier cases we think the results were not as good as those treated more recently, so far as cure

Fig. 4 (case 2)—Condition of antrum *A* Nov. 24, 1924 showing complete destruction of the floor of the antrum on the right side to be compared with the healthy antrum on the left. *B* showing the patient still well April 23, 1930 with the reformation of the floor of the right antrum.

can judge by the primary healing. We have gradually increased our total quantity of irradiation. By this method we have treated 111 patients. Of these, thirty-nine have become symptom free and are at present apparently well after a period of from one to five years, and nineteen are still under treatment and expected to recover. Treatment was interrupted in four patients, five patients cannot be traced, and forty-four are dead. It is our impression that 50 per cent of the patients with cancer of the mouth should recover if treated at once, thoroughly and skilfully by this method as soon as they come under the care of a physician, and 75 per cent should recover when patients can be taught to apply for treatment earlier.

A record of the thirty-nine symptom-free cases is as follows: less than one year, 4 cases; from one to two years, 11 cases; from two to three years, 8 cases; from three to four years, 5 cases; from four to five years, 4 cases; from five to six years, 7 cases.

Our records contain many advanced cases. In eighty-two of these patients there were palpable lymph nodes. No one can be certain that palpable lymph nodes are malignant, but certainly from a clinical standpoint they must be regarded as malignant for the sake of proper treatment.

Surgical dissections show from 12 to 20 per cent to be nonmalignant. Of the eighty-two patients with palpable lymph nodes, twenty-three have recovered, nine are under treatment, forty-four are dead, three cannot be traced, and three discontinued treatment. This shows a proportion (28 per cent) of recoveries with glandular involvement that is probably equal to the results obtained by block dissection and with less suffering on the part of the patient and less interference with the radiation treatment.

We have had twenty-three patients in whom the cancer had extended into the neighboring bone. Of these patients, nine have recovered (39 per cent), three are under treatment, one cannot be traced, nine are dead and one discontinued treatment. This has seemed to us most remarkable. We believe that if the involvement is extensive, this cannot be expected. Three cases with bone involvement were also demonstrated to us as headed by Gendreau of Montreal.

ADVANTAGES OF PURE GAMMA RADIATION TREATMENT

The advantages of pure gamma radiation treatment are as follows:

- 1 It is painless at the time of application, though it causes soreness and swelling in the mouth at the height of the radiation effect.
- 2 It does not require an anesthetic.
- 3 It does not require hospitalization.
- 4 It does not produce mutilation.
- 5 It usually does not produce constitutional symptoms.
- 6 The skin effects, when carefully managed as directed, are of no consequence.
- 7 In tongue cases, the function of the tongue is preserved.
- 8 It usually causes the disappearance of metastatic lymph nodes. When these are sluggish, we sometimes insert radium needles into the lymph node. If the glands break down they are removed surgically.

DISADVANTAGES OF PURE GAMMA RADIATION TREATMENT

The disadvantages of pure gamma radiation treatment are as follows:

- 1 It is exceedingly expensive because one is only using a small portion of the total radiation.
- 2 It is not very practical to hire radium because one must pry while it is in transit.
- 3 A considerable quantity of radium must be available if one is treating a number of patients and only one who treats only a few patients generally lacks experience.
- 4 It interferes with the occupation of the patient during a period of at least a month.
- 5 It requires the constant or daily supervision of the experienced radiologist and cannot be turned over to technicians.

6 It requires the constant cooperation of the patient, which may be difficult to obtain

7 The prolonged treatment that is necessary may be interrupted by ignorant patients who do not appreciate the seriousness of the disease or who consider themselves well prematurely

8 The greatest possible precautions against undue personal exposure must be taken by the radiologist and the technician because of the large amounts of radium that must be used

ASSOCIATED TREATMENT

1 All use of tobacco must be prohibited

2 A roentgen examination should be made of all the teeth and of the alveolar process

3 All diseased teeth should be removed, either at the beginning or as soon as sufficient radiation has been given to devitalize the cancer cells so that they will not be extended by the traumatism

4 The mouth should be cleansed and kept clean. This will require much care and gentleness

5 There should be a complete blood count made at the beginning and repeated from time to time during the treatment. If the patients are anemic, appropriate treatment must be instituted

6 A Wassermann test should be made in most cases, for a large percentage of cancers of the mouth develop on old syphilitic lesions. Therefore, the presence of a positive Wassermann test does not eliminate the diagnosis of cancer and should not delay the treatment. Likewise, a microscopic diagnosis of cancer does not eliminate the possibility of associated syphilis. Both a microscopic diagnosis and a Wassermann test are usually advisable in each case

7 When a section is taken for a microscopic examination, radiation treatment should be used either before or immediately afterward and should be continued until the lesion is proved not to be a cancer, or until sufficient radiation has been used to cure the cancer. The fact that one considers a section necessary shows that cancer is a possibility. Under such management, with immediate associated irradiation, we have never seen any bad effects from doing a biopsy

8 The nourishment of these patients must be carefully provided for, otherwise they are likely to avoid food and lower their vitality

1321 Spruce Street

ABSTRACT OF DISCUSSION

DR GEORGE W GRIFF Pittsburgh I hope the significance of this presentation is impressed on the audience. I take it that the manner in which radium is applied is of more importance than the mere fact of treating some disease with radium. Those who use radium perhaps forget this and others perhaps fail to realize this point at all. The technic of radium treatment must be learned. If one will duplicate the results of the authors he must learn how to do it. I felt for many years that the surface application of radium in the mouth was the preferable method of treatment to interstitial irradiation. I am glad to see that Drs Pfahler and Vastine more or less corroborate my belief in this respect. All know the drawbacks to interstitial irradiation in the mouth and certainly the average radiologist will stand a much better chance of curing a larger percentage of cases if he tries to perfect himself in the technic of surface application than he will by the use of implants. There are circumstances of course in which surface application is impossible but wherever it is possible it seems to me the chance of recovery is greater. I decide whether I shall use surface application or implants by the fact as to whether it seems possible to keep the radium in its proper

location for a sufficient length of time to give the full dose. If that can't be done of course it is useless to attempt the surface application. Undoubtedly a great part of the unusual results shown by the authors are due to an added method of treatment and that is external application of large doses of radium. This, I think, is new to most of us. Certainly the results shown here and the treatment of metastases open up a large field for thought. It has been my experience as a rule, that when patients with carcinoma in the mouth develop large visible cervical glands the case is practically hopeless, and yet the authors have shown several cases in which these metastases have disappeared entirely. Any method of treatment that will allow of such results is certainly a great advance. Surgery is not the final and ideal method for the treatment of cervical metastasis, that is sure. It looks as if here was a method which will increase the number of cures.

DR J E GENDREAU, Montreal This method can give very good results, not only in that special part of the body but in other parts. For instance, if one wants to introduce into the axilla a great amount of radiation through external agents, radium or x rays, heavy filtration must be used. If only one or two erythema skin doses per port of entry can be given much of that radiation will not be sent deeply, but if as much as five erythema skin doses per field through a heavy filter can be used, there will be much more in the axilla. It is just the same for radium. When about 50,000 millicurie hours is given, a very thick filter must be used to avoid producing skin lesions. I have been following the method for many years and I had the privilege of showing it to Dr Ernst and Dr Pfahler in Montreal in three cases of cancer of the floor of the mouth with invasion of the bone and metastasis, that had been apparently cured for many years. These cases had been treated by surface applications only inside and outside the mouth and the result was a complete disappearance of the nodes and of the tumor in the mouth. It would have been difficult to obtain the same results with low filtration. I never had, though the wonderful results that the authors have shown in the reconstruction of the divided bone itself in many cases I had destruction.

DR GEORGE E PFAHLER, Philadelphia We have no rule that we can lay down for the treatment of cancer of the mouth. Every case must be individualized and the treatment must be adapted to the individual case. We do use interstitial radiation but we do not usually begin with interstitial radiation. We use a surface radiation and when we get to a standstill in a lymph node, for example, or an induration remaining in the tongue, we insert radium needles to get some additional help. But it is my opinion that whenever interstitial radiation is used we should add surface radiation for the congestion that is set up by the interstitial radiation at a distant point where cancer cells may still be viable. Those cells may be stimulated to grow unless one adds some surface radiation.

Expert Witnesses—Just as we have in the practice of medicine the so called general practitioner who must study and treat all types of disease and conditions presented to him so we have had in times passed in the field of legal medicine those who attempted to qualify as advisers of the court in the elucidation of problems of widely varying character. However the advances in the field of scientific medicine have been so marked in recent years that no single mind is able to carry the details of all of the many branches. The questions presented for solution in courts of law are so intricate oftentimes that it is not to be expected that any but carefully trained pathologists, neurologists, chemists, surgeons, obstetricians, chemists and other specialists would be in a position to act as real judicial advisers. In many cases the aid of several experts must be invoked as the questions involved may necessitate a comprehensive knowledge of different fields. Hence the courts demand that only those especially qualified by experience and special study along definite lines shall be called upon to aid in the clearing up of problems presented for solution. Such witnesses or advisers are known as expert witnesses and are asked to testify as to their opinions or as to the facts based on their special examinations of the case or as to the deductions to be made from the facts set before the court by other witnesses.—Webster R W Legal Medicine and Toxicology Philadelphia W B Saunders Company 1930

REMOVABLE INTERNAL FIXATION IN FRACTURES *

W B CARRELL, M D

AND

P M GIRARD M D

DALLAS, TEXAS

An analysis of the fracture problem by committees making careful surveys in large groups of cases during the past few years, has served to establish certain definite principles that must be followed though methods for carrying out these principles will differ with surgeons according to their training and equipment. The final result, a return to function, may be equally good with widely variant methods.

In appraising a fracture one must see more than a broken bone. The ultimate goal, return to function, depends on the recovery of muscles and ligaments as well, for bones may unite in good position after rough handling, but the damage in soft tissue may be irreparable. A trained surgeon with the right conception of the problem will be able to reduce most fractures by manipulation or traction and direct the subsequent treatment for the patient's final recovery. It should therefore be the aim of the orthopedic surgeon to perfect the technique of closed reductions. This will result in the successful treatment of many fractures that would come to open operation under less skilful care.

Under ideal conditions, however, there are some fractures that can be treated more successfully by internal fixation of the fragments, and the surgeon should be prepared to follow this method when indicated. Additional equipment necessary is knowledge of bone

in bone surgery, one may consider open operation in fractures of the following groups:

- 1 Certain fractures about joints when muscle contraction prevents approximation by the closed method. Transverse fractures of the olecranon and patella are instances.
- 2 Fractures extending into weight-bearing joints with resulting, uneven surfaces opposed.
- 3 Nonunion.
- 4 Malunion, when sufficient deformity is present to interfere with function.
- 5 Recent fractures, after failure by well planned closed methods.

Fig 2—A fracture of lower third of the femur B fragments held by staple

As there are different plans for successfully reducing or splinting fractures there are likewise different methods for fixing them in operative work, with equally good results. Removable internal fixation, an old principle practiced by Allen Thompson and others, has merit in selected cases. It is our purpose in this paper to suggest some modifications to the method which makes it applicable to a wider range of conditions. It does not meet every demand for an ideal fixation device, neither do other instruments in general use. This fixation is not rigid, unless combined with plaster, and therefore it is difficult to get early motion in the adjacent joint. The pin projects through the skin and may favor infection. From our experience, however, this danger is not warranted.

In a limited number, but including several varieties of fractures, we have found that fixation is adequate, and, by hinging the plaster at the joint, motion may be instituted immediately after operation. With external fixation in plaster, the pin has a distinct advantage in controlling completely the tendency for angulation due to the contraction of muscles. This is observed regularly in the middle and upper third of the femur. The method is so easily and quickly applied that it changes a rather major operation to one of less exposure, less trauma and, therefore, within the sphere of a greater number of surgeons.

Depending on the type of fracture, three different devices have been used. For oblique fractures in the long bones and T-fractures in the joint, as the lower end of the humerus, femur or tibia, the screw is well adapted. It is made of stainless steel with a drill point and matching thread and is provided with an ordinary nut, which is tightened after the screw has firmly engaged the distal fragment. We have tried making a

Fig 1—A fracture of upper third of the femur B held by removable screw

surgery and adequately trained assistants who can carry out a scrupulous technic in the operating room. The average technic used in abdominal surgery would be disastrous if it should be followed in a series of bone cases.

With the background of good mechanical sense and familiarity with the principles of splinting and training

* Read before the Section on Orthopedic Surgery at the Eighty First Annual Session of the American Medical Association June 26, 1930.

* Owing to lack of space this article is abbreviated in THE JOURNAL by the omission of several illustrations. The complete article appears in the authors' reprints.

shoulder instead of a nut, but rejected it, because of the uncertainty in having a perfect fit for the case at hand. A sleeve placed over the screw and the nut outside, forcing the sleeve against the near fragment, was tried but found to be more cumbersome and less effective.

For application of the screw shown in the accompanying illustrations, the bones are approximated and held with a small narrow clamp. Two carpenter hand drills are provided. One drill, slightly larger than the screw, is placed obliquely through the nearer fragment. The other, smaller than the screw, is passed through the distal fragment. The screw, held in the chuck of one of the hand drills, engages firmly in the distal fragment and the nuts are then screwed tight with pliers against the nearer fragment. The screw is set obliquely so that the lines of stress may cross the screw instead of running parallel with it. In the latter position, the threads would receive all the strain and be less stable. The incision is completely closed and the screw extends about half an inch beyond the snugly applied dressings. Two light splints of plaster are added and applied evenly over the distance of the fractured bone but not including either joint. One of the splints incorporates the screw, and the two are bandaged securely and permitted to set. These inside splints fix the screw and because of their accurate fit do not permit movement of it, as would be present in a large plaster including the pelvis and entire leg. The outside plaster may be hinged at the elbow or knee for early motion. The screw should be left from three to four weeks and can be removed easily without pain. A pressure pad should be substituted in the case of a fractured femur.

In transverse or slightly oblique fractures, with insecurity after reductions, the two pronged fork may work admirably. After reduction, the bones are held with forceps on each fragment and the fork is driven through the cortex as one would hammer a nail. It is important that the holes should be started with a drill, otherwise a fragment may split out and defeat the purpose. The pin emerges through the dressing and is

wound. On splitting the bar completely, it may be removed in sections and used on a simple fracture with easy removal.

These simple devices have been of greater value in fractures of two or three weeks' duration when manipulations and imperfect traction have failed to secure a satisfactory position. The argument might be made that good early treatment would prevent such conditions, but the facts are that consulting fracture surgeons will continue to see them and will wisely elect to open some rather than risk further trauma in late manipulation or

Fig. 4—A nonunion (nine months) in fractured humerus. B union four months later. Osteoperiosteal bone graft and screw.

unless traction. The method has been used several times in cases of nonunion. The fragments were freshened and fixed securely with a screw, after which osteoperiosteal grafts were placed in the usual manner. Figure 6 is a nonunion of the femur of eighteen months' duration, in the case of a healthy man, aged 23. The screw and periosteal grafts were used and consolidation was complete in four months.

The choice of bone graft operations is not under discussion, but those who prefer osteoperiosteal grafts will find temporary fixation one of the factors in preventing failure by the method. The most definite indication for the screw fixation is in joint fractures with widening of the articular surface.

Figure 7 is a fractured humerus with good traction for three weeks without reduction. The deformity was reduced to a hair-line fracture by open operation and fixation was so complete by use of a screw that motion was immediately instituted and recovery was complete in three months.

The plan of removable fixation is not proposed to meet all requirements in an operation in fractures but in selected cases

we have found it adequate easily applied and worth a place in the armamentarium of the fracture surgeon.

701 Maple Avenue at Wellborn

ABSTRACT OF DISCUSSION

DR. ROBERT D. SCHROCK, Omaha: The procedure of Drs. Carrell and Girard I believe to be a very timely one. Their emphasis, however, on the introduction of the minimum amount of foreign material to obtain fixation I believe should be urged just a little bit further. Their ideas are so much in agreement with my own practice that I cannot find sufficient points of

Fig. 3—A fractured olecranon of four days' duration. B, fragments held in apposition with elbow at right angle position by removable staple. C, another similar fracture held by removable screw.

fastened to the plaster in the same manner as described for the screw. It is obviously less secure but meets every requirement in some cases and is even more quickly and easily applied. The third device is, in principle, a miniature bone clamp. Two spurs are made on the end of a steel tube and through the tube a threaded bar is split at one end to form the two arms of a clamp and when tightened by a nut on the outside, effects a permanent grasp on the bone. This instrument was designed especially for compound fractures and even though bulky can be removed through the open

difference to present a desirable opposition to the ideas presented. The minimum amount of foreign material introduced adds to safety in the necessary open reduction. I think the authors did not stress in their discussion the added necessity of adequate external fixation is well. More than that, in the femur, with the minimum internal fixation, the essential fixture is traction efficiently applied in order to prevent the external bowing of that femur, particularly in the middle third. I should like to have the authors tell something of the difficulty of removal of the screw, particularly with the nut on it. It seems to me that there will be a little difficulty in removing that without local

that if it is left in too long it will cause irritative changes in the bone. These nonabsorbable materials usually should be removed within a period of from three to six weeks. The method of Drs. Carrell and Girard apparently has these advantages over those previously advanced. It is easier to apply, the fixation is stronger and it is easier to remove. The disadvantage may be that they failed to stress the necessity of external splinting. In all these cases of splinting internally, they must also be well fixed on the outside.

DR ALFRED J. BUKA, Pittsburgh. Drs. Carrell and Girard have shown that foreign material, especially metal, has no business generally to remain in fracture sites ad infinitum. I think the idea of removing such splints is right and that leaving them at a fracture site for an indefinite period is out of place and often dangerous. Any one doing reconstruction and fracture work has found it necessary from time to time to take out some of this hardware. I feel that setting out with a plan for a definite time of removal of metallic substances put in a fracture site for fixation is more valuable than anything pertaining to their use.

DR S. C. WOLFFBERG, Chicago. If a patient is subjected to an open operation for reducing fractures, and an osteoperiosteal graft is done, it should not be necessary to put in any external material, as staples or anything else. If the plaster cast or splint or whatever external support is used is applied adequately and has the right kind of assistance, it should not be necessary to put in any foreign material. I don't know why there is so much objection to putting in an ordinary staple when the fracture is opened and the ends are brought together. I do not have to take them out if they are put in properly. In more than a hundred cases I have not had to remove more than two or three staples and they were all at the anterior portion in the middle third of the tibia. They were superficial and both cases were old. One thing that is most important is the necessity of not repeating manipulations in trying to bring the ends together and not doing any open operation with the hope that union will result.

DR WALTER G. STERN, Cleveland. Being the only one in my memory who has ever come before this section to read a paper on the nonoperative treatment of compound fractures, I

Fig 5—A compound fracture B removable clamp holding fragments. The iron bars connect the foot and knee casts allowing for dressing of wound and firm fixation. Union three months later.

anesthesia. I have been using little pins for internal fixation of fractures, devised by Dr. John P. Lord. They are made of diamond point wire. A machine drill is used for making the hole, the diamond point being too short to cut the hard cortex of bone. The removal of the drills is the easiest part of the procedure. At the end of about the third week they can be pulled out with dressing forceps without pain. The drills are made in various sizes to meet the indications. I have been using phonograph needles for the small metacarpal fractures but this type of drill is sufficiently heavy to hold femurs.

DR HARRY E. MOCK, Chicago. The minimum amount of foreign material should be used in any of these open reduction cases, and preference given to external fixation whenever possible. Each year I am reducing the percentage of open operations for recent fractures more and more. I now operate in only 2 per cent of early fractures. I long ago abandoned the Lane plate. The various fixation screws shown by the authors are very ingenious. These screws give the minimum amount of foreign material for fixation, but there is the same danger of osteoporosis around the site of application of the screw and therefore do add a certain amount to the danger of infection and of nonunion. I get a great many cases of reconstructive surgery. This last year I have had two cases of markedly deformed elbow joints the result of fractures of the lower end of the humerus in which screws were applied as a method of fixation without putting on a Lane plate. Every year brings forth a certain number of examples of worse deformities and more prolonged disabilities, the result of attempted open reduction and fixation of fractured fragments than could possibly have resulted from even a poorly closed reduction of the original fracture. I doubt the advisability of advocating to the rank and file of the profession the use of foreign material in fixation of fractures. Papers on technique for open reduction should always emphasize the fact that only a very small percentage of fractures require open reduction.

DR JOSEPH E. WHEELER, Jefferson Barracks, Mo. Ordinarily such methods are used in the treatment of fractures as traction, manipulation, external fixation and countertraction but in some fractures, oblique or spiral or those near the joint extending into the articular surfaces of the joint it is necessary to use some internal splinting. These splints are of two kinds, absorbable and nonabsorbable. The nonabsorbable material is stronger and where there is any great stress, the nonabsorbable is usually employed. The disadvantage in the nonabsorbable is

Fig 6 (Captain H.)—A nonunion of femur of eighteen months duration B open reduction fixation by removable screw plus periosteal bone graft C good union in four months.

cannot help but warn you of tempting the medical profession in general with the assuring principle that it is safe to operate immediately on the bones of a compound fracture for the purpose of correcting the deformity. I am sure a skilful technic will permit a trained operator to put in staples or to use the ingenious combination of nut and bolt that has been shown here, but I do not think the method should be spread broadcast in a medical journal so that the ordinary rank and file of the men treating fractures will think that they can operate on the bones of compound fractures and put in metal devices and get away with it, because in my experience in my neck of the woods it can't be

done. The great danger in compound fracture is not nonunion or malposition, it is infection, and when foreign material is put in or operation is done on the bones of a compound fracture—the resistance of which is already weakened by the trauma—nothing is added to the ability to resist infection. The first thing one must do in a compound fracture is to overcome the ever present danger of infection and if after eight or ten days this danger of infection is over, one must let his conscience be his guide, but the infection should be overcome first. Drs. Carrell and Girard have shown in certain of their cases that even after two or three weeks they have been able to reduce the fracture, hold it with their ingenious staple and get union, so one need not be afraid of waiting eight, ten or fourteen days for the danger of infection of the compound fracture to be overcome before performing any operation or extensive manipulations.

DR W B CARRELL, Dallas, Texas. Dr Stern's remarks are pertinent to a discussion on open operation in compound fractures. I shall not argue this point, but for those who believe the potential factors for infection in some cases are so great that conservative treatment is dangerous, this miniature bone clamp, following debridement of the wound, serves the excellent purpose of holding the fragments in position without penetrating

Fig. 12—A, removable clamp particularly adapted to compound fractures in three pieces not including two nuts. B, removable screw for internal fixation. C, removable staple for internal fixation.

the bone or in any way interfering with subsequent treatment by surgical solution of chlorinated soda or petrolatum packs. Notching the fragments will in many cases be adequate. Displacement is more likely to occur during application of plaster and delayed closure would certainly minimize this misfortune. The method, however, generally applied, seems fraught with possible danger of a break in surgical technic. With regard to difficulties in removing the screw, attention is directed to the type of nut with the external surface rounded to permit less friction when backing through the soft tissues. Removal is quite easy and has not been complained of by the patient. The staple is slightly more difficult and the removal can be facilitated by making the skin opening long enough to permit undue tension.

Arthritis Without Bacteria in Joints—Friebberg has shown that arthritis can occur without bacteria entering the joints and was able to produce cartilage destruction, proliferation of the synovial membrane and new bone formation in rabbits by injecting intra-articularly the sterile filtrate from a strain of Flexner's dysentery bacillus. As control fluids he used salt solution, horse serum and dilute lactic acid which on injection did not produce a similar arthritis. These researches may possibly supply one plank in bridging over the gap between the infective and noninfective theories for if sterile filtrates of bacteria can produce the lesions of arthritis deformans, toxic bodies resulting from metabolic disturbances may also be capable of setting up similar changes.—Powerton F. I. and Schlesinger B. Recent Advances in the Study of Rheumatism. Philadelphia: P. Blakiston's Son & Co., 1931.

THE TREATMENT OF PEPTIC ULCER WITH GASTRIC MUCIN

PRELIMINARY REPORT *

SAMUEL J. FOGELSON, M.D.

CHICAGO

The ideal therapeutic agent for use in combating the irritative action of gastric juice in peptic ulcer is one that will neutralize or combine with the acid without materially stimulating or depressing gastric secretion, without materially affecting gastro-intestinal activity, and without having a general systemic action. Although alkaline powders have been and are being used in the treatment of peptic ulcer, it is well known that they are not ideal.

In the literature on gastric secretion, the capacity of mucus to lower the free acid in the stomach is repeatedly suggested. In 1879 Heidenheim believed that mucus was alkaline and later Pavlov¹ suggested that it was the mucus which lowered the free acidity of the stomach by neutralization. Ivy² made pouches of the pyloric antrum in dogs and found the secretion of these pouches to be "mucoid, viscous, tenacious, transparent, odorless and slightly salty. It resembled egg white in appearance and consistency, was slightly alkaline with a p_H of 7.0 to 7.5 and neutral to litmus." Lim,³ in an exhaustive article on the relationship between gastric secretion and basal secretion of the stomach, states that "it thus seems not unlikely that the colloid nature of mucus accounts (adsorption of alkali) for the titratable total acid found with the lowest secretory rates." He adds that "at lower secretion rates the concentration of mucus is unquestionably higher especially in the case of entire stomach juice, containing pyloric secretion which is continuous and little altered by secretory activity in the fundus."

These physiologic observations suggested gastric mucus as an ideal antacid in that (a) it combines readily with the free acid, (b) it is a natural substance which plays normally a protective, soothing and lubricating role in the functioning of mucous membranes, and (c) its secretion or ingestion causes no chemical disturbances in the body and no unfavorable effect on gastro-intestinal secretory or motor activity. To evaluate gastric mucus as an antacid, it was necessary either to stimulate the secretion of mucus by the gastric glands or to administer it by mouth. Increasing the bivalent anions in the circulation should stimulate secretion from the gastric mucous glands⁴ but in these experiments on Pavlov pouch dogs no definite effect was discovered. The alternative procedure, then, was to prepare mucus from other sources and administer it orally to experimental animals and patients with the hope that the measurable free acid would in this way be definitely lowered and the lower secretion rates of Lim would be reproduced.

An ideal preparation of mucus would have the characteristics of the mucus that Ivy isolated in his experiments on the pyloric pouch. With the cooperation of Dr. Fred Fenger of the Armour & Co. Research

* From the Department of Experimental Surgery, Northwestern University Medical School.

Laboratory in Organotherapeutics mucin was prepared by precipitation from a dilute hydrochloric acid solution of gastric mucosa at a pH of 4.5 after the addition of an equal volume of alcohol. When dried and neutralized to a pH of 7.0, it is mucoid, viscous, readily soluble in acid and alkali, faintly soluble in water and has a high combining power. One gram of this powdered mucin combines with about 15 cc of 0.5 per cent hydrochloric acid.

Chart 1—Typical gastric analysis on feeding dogs 1 ounce of mucin, gelatin and egg albumin. From the free and total acid values shown here it is obvious that mucin as at present prepared is a slightly greater gastric stimulant than either egg albumin or gelatin.

On chemical analysis this powder was found to contain moisture, 5 per cent, ash, 14.65 per cent, sodium chloride, 2.50 per cent, organic chlorine, none, total nitrogen, 9.93 per cent, phosphorus pentoxide, 4.45 per cent.

EXPERIMENTAL RESULTS

The mucin prepared from the hog's gastric mucosa and used in this experiment has a high combining power with free acid but does not depress gastric secretion. In fact, when equal quantities of this mucin in solution, egg albumin or gelatin, respectively, were put into the stomachs of Pavlov pouch dogs through a stomach tube, the mucin led to a slightly greater secretion of acid than either gelatin or egg albumin (chart 1). It is well known that both egg albumin and gelatin are weak excitants of the gastric glands and for this reason they were contrasted to the mucin. Our results show that the mucin as prepared at present is only a mild gastric secretory excitant. These experimental results have been confirmed by Drs. Ivy and Kim, who report the following from the hog gastric mucin with which I supplied them: "(1) The hog's gastric mucin used has a high combining power (1 Gm combining with

Chart 2—This chart supplements chart 1 and demonstrates that our preparation of mucin put in the stomachs of Pavlov pouch dogs will lead to about the same quantity of pouch secretion as gelatin or egg albumin.

from 12 to 15 cc of tenth normal hydrochloric acid), (2) it does not irritate the gastro-intestinal mucosa, (3) it mildly stimulates the gastric glands and in its present form it excites the gastric glands on being perfused through a pouch of the entire stomach, which proves that it contains secretagogues.

When 2 ounces of mucin, egg albumin, gelatin or meat, respectively, were introduced by stomach tube into the stomach of the Pavlov pouch dogs and the dogs were excited to secrete gastric juice at the beginning

of the experiments by an adequate dose of histamine, it was noted that there was complete absence of free hydrochloric acid only in the stomachs containing the mucin, whereas in the Pavlov pouch in all cases secreted the usual free acid. These results show that the mucin has a high combining power with free acid *in vivo*. Chart 3 shows a comparison of the free acid in the stomach when immediately after histamine stimulation 2 ounces of mucin, gelatin, or egg albumin and 4 ounces of meat, respectively, were put in the stomachs of Pavlov pouch dogs.

Of further interest were the results obtained from feeding Pavlov pouch dogs 1 pound of meat in which there was mixed half an ounce of powdered mucin. Meat itself, of course, has a high combining power, but in the controls that were fed meat alone some free acid was present in these dogs' stomachs throughout in observation period of from five to seven hours or until the stomachs were empty. But this free acid was absent in all cases when the half ounce of mucin was added to the meat, this was especially significant as the pouches in all trials showed the expected stimulation (chart 4).

Encouraged by these results in animal experiments and because I was able to obtain a preparation of mucin

Chart 3—Demonstrating that after adequate stimulation by histamine as shown by the pouch secretion only mucin will keep the free acid in the stomach at zero. Only the free acid value are plotted in the chart. A is free acid value of the pouch secretion. B is free acid value of gastric contents with 4 ounces of meat in the stomach. C is free acid values of gastric contents with 2 ounces of gelatin in the stomach. D is free acid values of gastric contents with 2 ounces of egg albumin in the stomach. L shows absence of free acid with 2 ounces of mucin in the stomach.

free from intestinal parasites, ova and other objectionable features, I extended the experiments to cases of peptic ulcer in man.

CLINICAL RESULTS

Since January, 1930, twelve patients with typical ulcer histories were available. The roentgen appearances in ten of these were those usually interpreted as characteristic of duodenal ulcer. One of the remaining patients had a gastric resection and the other had a gastro-enterostomy. In both of these, pain after eating was the major complaint. The duration of symptoms varied from two to seven years and all of the patients had been on the usual alkalinizing regimen together with the customary nonirritating diet with only temporary relief. One patient had marked retention after ten or twelve hours.

The general procedure was to give each patient an ounce of powdered mucin prepared as described with each meal and from 20 to 40 grains in tablet form either hourly or every half hour when the patient had severe pain or when the fractional Ewald test meal showed unusually high free acid. The ounce dose of mucin was not easy for the patients to take because of its viscous character, but Miss Tufts, the dietitian at Wesley Memorial Hospital, solved this problem by

incorporating it in ice cream or similar frozen foods, as well as in thick drinks such as malted milk. Further treatment consisted only of the usual bland, convalescent ulcer diet.

In all twelve patients the subjective symptoms disappeared within three days of treatment, the most gratifying feature being the persistent absence of pain, which did not recur despite two grave dietary indiscretions in two patients with alcoholic tendencies. The periods of observation have, however, been only from

Chart 4—This contrasts feeding Pavlov pouch dogs a pound of meat alone with a pound of meat mixed with half an ounce of mucin. There is no free acid in the stomach when the mucin is added as shown by curve C. A total acid value of pouch secretion. A free acid value of pouch secretion. B total acid value of gastric contents with meat feeding. B free acid value gastric contents with meat plus mucin feeding. C total acid value of gastric contents with meat plus mucin feeding. C absence of free acid in gastric contents with meat plus mucin feeding.

two to five months. The patient with retention now has a normal emptying time. As yet, difficulties have not been encountered from excessive quantities of mucus in the stools nor has any patient shown any ill effect from being fed such large quantities of mucin.

COMMENT

It is realized that periods of observation varying from two to five months cannot justify any thought of cure in this small series of twelve cases. But since mucin from a theoretical and experimental point of view proves to be practically ideal, an extensive clinical trial is indicated. The mechanism that afforded the relief from symptoms may be the combination of the free hydrochloric acid with the mucin, although another important factor is present that cannot be ignored. J. E. Whitlow,⁵ studying the protective role of gastric mucus against the proteolytic action of gastric secretion, concluded:

1 Gastric mucus does delay and inhibit—though not prevent—the diffusion of hydrochloric acid and pepsin.

2 The rate of diffusion of hydrochloric acid through gastric mucus is inversely proportional to the depth of mucous layer and inversely proportional to increase in viscosity of the mucus; the diffusion of pepsin is directly proportional to the time required for the hydrochloric acid to diffuse through the entire depth of the mucous layer.

3 The presence of tenth normal hydrochloric acid in gastric mucus hastens the rate of diffusion of pepsin through a layer of mucus.

4 The fact that gastric mucus covers the mucous membrane of the stomach with a viscid tenacious coat that retards digestion and diffusion of gastric juice as shown by *in vitro* experiments makes it impossible to deny the protective role of this secretion against autodigestion of the stomach.

5 The most direct evidence of all however is the fact that when the mucus is wiped away with a cotton swab and tenth normal hydrochloric acid or normal gastric juice is applied bleeding occurs and when merely swabbed with equal vigor and mechanical irritation no bleeding occurs. It becomes a self-evident fact therefore that mucus protects the gastric mucosa against the action of gastric juice.

5 Whitlow, J. F. The Protective Action of Mucus. Master's thesis, Loyola University (unpublished).

Similar results are reported by Klug⁶ and it is highly probable that the relief from symptoms obtained from feeding the mucin preparation was secondary to two factors. First, the mucin coated the ulcer and protected it against the proteolytic action of the gastric secretion, and, second, through its high combining power with free acid it united with enough hydrochloric acid not only to neutralize the corrosive action of gastric juice but also to prolong the rate of dialysis of pepsin through the now present protective mucin layer. Obviously, both these factors would be important in affording relief from pain and in hastening healing.

SUMMARY

1 Gastric mucin prepared from hog's stomach is only a mild excitant of gastric secretion.

2 Gastric mucin has a high combining power. Two ounces of mucin placed in the stomach of the dog was more than sufficient to combine with the acid secreted in response to the injection of 1 mg. of histamine.

3 When half an ounce of mucin was mixed with a pound of meat and fed to a dog, free acid did not appear in the dog's stomach throughout the period of observation of from five to seven hours.

4 Complete relief from symptoms for varying periods of from two to five months was afforded to twelve patients with classic histories and roentgen appearances of peptic ulcer by feeding them about an ounce of hog's gastric mucin three times a day with their meals in addition to about 30 grains of mucin in tablet form hourly throughout the day.

USE OF VITAMIN B IN DIETS OF INFANTS

FURTHER OBSERVATIONS*

B. RAYMOND HOOBLER, M.D.

DETROIT

Since my former report¹ there has been a prodigious amount of work done covering many phases of vitamin B. The chemical and biologic properties have received the greatest attention, as evidenced by the many reports of research that have been published. The problem seems to be world wide if one takes into account the geographic sources of these studies. The greater part of the work is still being done on animals particularly on birds a group that is most susceptible to this deficiency disease. The chemists also have been exceedingly busy in this field. I shall give a summary of the most recent observations of biologists and biochemists before proceeding to the original work with which this paper deals.

The most striking development in the studies of vitamin B is the discovery that there are several different factors in what was originally considered as vitamin B. Goldberger² has separated the pellagra-preventive factor and that portion is now known as vitamin G. The term vitamin B should be restricted to the anti-neuritic fraction. The separation of these two fractions

(Klug, F. Arch. internat. de physiol. 5: 297-317, 1907.
* Read before the American Pediatric Society, Montreal, June 17, 1930.

2 Goldberger, Joseph, Wheeler, G. A. and Schrell, W. H. A Study of the Black Tongue Preventive Value of Treated Commercial Casein Together with a Test of the Black Tongue Preventive Action of a High Protein Diet. Pub. Health Rep. 45: 2-3 (Feb. 7) 1930.

is accomplished by heating, the antineuritic portion being heat labile and the pellagra-preventive being the heat stabile portion. Williams and Waterman³ believe that a third portion, which is intimately connected with the processes of digestion, will also be separated. Until recently it was believed that the animal organism could not synthesize vitamin B, but recently Bechdel and his co-workers⁴ demonstrated that this could be done in the rumen of cattle through bacterial action. This may lead to a new source of vitamin B. With the ability to separate at least two factors from the vitamin B complex, the analysis of various food products has become necessary, it is interesting to note that certain foods contain much more vitamin G and others much more of the antineuritic factor, so that a complete restatement of food values in these particulars is necessary.

Lactating animals have been shown to require from three to five times more vitamin B complex to maintain lactation than they need during nonlactating periods. There has been demonstrated a relationship existing between the basal food products and vitamin requirement. An important research conducted by Harris and Moore⁵ showed that there exists a definite balance among vitamins E and G, by greatly increasing vitamins A and D in diets an otherwise adequate amount of vitamin B is made inadequate leading to death of animals. One should be careful not to overdose with cod liver oil and viosterol unless at the same time an increasing quantity of vitamin B is also added to the diet.

Studies on the symptomatology and pathology of vitamin B deficiency have been largely confined to animal experimentation and but few clinical reports on infants have been published. Several valuable contributions, however, have been made showing that definite cases of full-fledged beriberi exist in this country, by Dr. J. I. Waring⁶ of Charleston, S. C., by Dr. Scott and Herrmann⁷ of Louisiana, by Dr. Oscar Swineford, Jr.⁸ in Virginia, by Dr. L. S. Chipman⁹ in Panama, and also by Dr. Sidney V. Haas¹⁰ as occurring in New York.

It will be seen, then, that the disease is not confined to the tropics and therefore the symptomatology of evident beriberi should be constantly in mind in dealing with more or less obscure nutritional conditions here in North America. It is my conviction, however, that our infants are menaced by a partial lack of vitamin B rather than by a complete deficiency. The former condition is much more difficult to diagnose than outspoken beriberi, in which the symptomatology has been compiled by observers in Japan and the Philippines.

The signs shown by the infant whose diet is only partially deficient in vitamin B differ markedly from those of infantile beriberi and may range all the way from fretfulness and anorexia to noticeable loss of

weight and rigidity. Contributions referring to partial deficiency have recently been made by Dennett,¹¹ Blossom,¹² West,¹³ and Morgan and Barry.¹⁴

Both the contributions on true beriberi and on partial deficiencies of vitamin B in infants are most welcome at this time when so much material is coming from the laboratories, particularly since experimental beriberi in animals differs somewhat from the human type, as pointed out by Cowgill.¹⁵

The original work to be detailed in this paper was carried out in the nursery wards of the Florence Crittenden Hospital, Detroit, in the service of Dr. Edgar Martner. Approximately 125 infants were studied over a period of five months. Whole milk dilutions were used throughout. A preparation of maltose and dextrin¹⁶ was the basic carbohydrate used in suitable quantities. Additions of vitamin B were made in the form of the extract of wheat germ and the extract of brewers yeast the potency of which had been tested on rats. This was added at the rate of 1 Gm. of wheat germ and 0.5 Gm. of brewers yeast extract to each ounce of the preparation of maltose and dextrin used. The infants were kept on the basal ration (whole milk dilutions plus maltose and dextrin) for a two week period. Records were kept of weight, total length, stem length, degree of spasticity, percentage of hemoglobin, appetite, and bowel conditions. At the end of this preliminary period the infants were kept on the same formulas and the wheat germ and yeast extracts were added in the proportions described and were continued for one month. Weights were taken weekly, but total and stem lengths were recorded only at the beginning and end of each period. The results are shown in the accompanying tables.

TABLE 1—Average Growth Monthly Stem Length

Breast fed	0.61 inch
Maltose and dextrin control	0.60 inch
Maltose and dextrin with vitamin B	0.75 inch

Table 1 takes into account growth in stem length. In taking both total and stem length, the methods used at the Merrill Palmer School were employed as described by Hejman and Hatt.¹⁷

The maltose and dextrin preparation with vitamin B additions made the best showing, the breast-fed controls next, and the maltose and dextrin preparation the poorest.

TABLE 2—Average Growth Monthly Total Length

Breast fed	0.90 inch
Maltose and dextrin controls	0.88 inch
Maltose and dextrin with vitamin B	0.91 inch

Table 2 represents the total average growth during a twenty-eight day period. Breast-fed infants grew

most, those fed with the maltose and dextrin preparation with vitamin B additions were a close second, while those given the maltose and dextrin preparation only showed considerably less growth

TABLE 3—Average Daily Gains in Weight

Breast fed controls (63 individual observation periods)	0.516 ounce
Maltose and dextrin controls (124 individual observation periods 98 per cent of breast 96 per cent of breast and 15 per cent of maltose and dextrine control)	0.601 ounce
Maltose and dextrin with extract of wheat germ and yeast (51 individual observation periods)	0.788 ounce

In table 3 the gains in weight are practically the same on breast, the maltose and dextrin preparation and the maltose and dextrin preparation plus vitamin B additions of a combination of extract of wheat germ and yeast

TABLE 4—Average Daily Gains in Weight

Food	Gain	Observation of Breast Feeding	Per Cent Gain
Breast	0.593 ounce	5	
Maltose and dextrine plus extract of brewers yeast 0.5 Gm	0.550 ounce	17	98
Maltose and dextrine plus extract of wheat germ 1 Gm	0.688 ounce	19	94
Maltose and dextrin only	0.794 ounce	12	89

In an attempt to determine which was the better, wheat germ or yeast extract, a study of fifty-seven infants during a period of two weeks was made (table 4). Again the variations in gain were so narrow that no definite conclusions could be drawn, but breast controls showed the highest average daily gain, the infants given yeast extract next, those given wheat germ held third place, and those fed the preparation of maltose and dextrin were in fourth place

TABLE 5—Rigidity *

Infant	Food	1st Mo	2d Mo	3d Mo	4th Mo	5th Mo
Joanne D	Maltose and dextrin	3+	2+	2+	2+	2+
Gloria B	Maltose and dextrin plus vitamin B	+	3+	1+	1+	0
Irena	Maltose and dextrin	+	4+	+	2+	1+
Jean D	Maltose and dextrin	4+		+	2+	0
Bernice M	Maltose and dextrin plus vitamin B		4+	4+	4+	3+
Douglas E	Maltose and dextrin	4+	3+	2+	1+	0
David A	Maltose and dextrin plus vitamin B		4+	+	2+	1+
Edward J	Maltose and dextrin plus vitamin B	4+	+	2+	2+	2+
Russel	Maltose and dextrin plus vitamin B	4+	4+	4+	1+	3+
Shirley M	Maltose and dextrin	4+	+	1+		
Robert H	Breast	3+	3+	2+		Brewers yeast used

*Twenty cases were noted but only those with marked rigidity graded from 3+ or more are given here

Neither the preparation of maltose and dextrin nor the preparation with vitamin B additions was able to clear up the spasticity in certain cases. About 20 out of the 125 infants studied showed varying degrees of stiffness. I believe this to be about the ratio found in the usual hospital ward devoted to feeding cases. It was evident that ten of these twenty cases required more vitamin B than was contained in the additions supplied. It has been my experience that brewers yeast concentrate or powdered yeast is a more effective way to supply the vitamin B complex and this is borne out by the observations of Blossom¹². It should be noted that one of the most marked instances of rigidity occurred in a breast-fed child. In 1926 in collaboration

with Macy and Outhouse¹ I proved beyond question that human milk was relatively low in vitamin B content. How rapidly the rigidity cleared up under brewers yeast concentrate is shown in the table

CONCLUSIONS

1 Wheat germ and yeast in the form of dried powdered watery extracts when added in the proportions of 1 Gm of wheat germ extract and 0.5 Gm of yeast extract to 1 ounce of a preparation of maltose and dextrin and fed to infants caused no appreciable gain in weight over controls who were fed on similar formulas without vitamin B additions

2 Infants given vitamin B additions showed a greater growth in recumbent and stem length than controls not given the vitamin B additions

3 About one out of six of the infants studied showed symptoms of rigidity. This symptom disappeared in all but six of the cases, indicating that the quantity of vitamin B needed by infants differs greatly, and that one should bear in mind that while the amount of vitamin B in the commercial carbohydrate preparations may be sufficient for certain infants, there are others who will require larger quantities

ANTIVENIN THERAPY IN
PURPURA *

MAX R. STOCKTON, M.D.

AND

GEORGE C. H. FRANKLIN, M.D.

NEW YORK

The following case report is submitted with the idea of stimulating further study in the use of antivenin in purpura

A. P., a healthy white soldier aged 23 for the past two years featherweight champion of the Canal Zone was admitted to Gorgas Hospital Dec 30 1929 for a submucous resection and tonsillectomy. His family history previous personal history and complete physical examination were negative. His Wassermann reaction was negative and the coagulation time and urine were normal. This man during his career as a fighter, had been struck on the nose many times and the bleeding that followed always ceased quickly. His left foot showed a small deep recent operative scar and he stated that the incision had healed rapidly and with but little bleeding.

December 31 a submucous resection under local anesthesia was performed. With the exception of the mechanical difficulties involved, due to the previous multiple fractures the operation was uneventful. For twenty-four hours after the operation there was an excessive amount of bleeding and the petrolatum packing was left in situ for forty-eight hours when its removal was followed by a severe hemorrhage. The usual local methods for the control of bleeding were employed and in addition he was given 10 cc of his own blood intramuscularly. Until Jan 16 1930 the patient was troubled with septal hematoma subsequent abscess formation between flaps periodic turbid bleeding and eventual sloughing of the septum. January 23 the patient developed an acute follicular tonsillitis with characteristic local and constitutional manifestations. He made a rapid recovery from this acute attack. As there had been no active bleeding since January 16 and the coagulation time was five minutes a local tonsillectomy was performed February 6. The operation was uneventful there was no undue bleeding and he left the operating room with dry fossae. Six hours after he had been returned to the ward from the operating room he developed a tremendous rapidly increasing extravasation of blood into his tongue and soft structures of his mouth and throat with such marked laryngeal involvement that it was necessary to perform a tracheotomy. February 7 at 11 a.m.

From the Gorgas Hospital

four hours after operation. At the time of the tracheotomy, bleeding was profuse—out of all proportion to the surgical procedure; however this was controlled by ordinary surgical means. One hour after tracheotomy he had a series of profuse hemorrhages from the tracheotomy incision. In the fifteen minutes that elapsed before he was again prepared for operation he went into marked shock and fatal exsanguination was feared. The incision was opened and the bleeding finally controlled by numerous ties and sutures.

Decannulation was performed February 11 four days after tracheotomy, the extravasation in the upper respiratory passages having been largely absorbed. He improved materially until February 22 when without apparent reason he had a profuse alarming nasal hemorrhage which despite all effort of control lasted in varying degree until February 26.

The therapeutic agents that had been employed up to this time were as follows: intramuscular injection of the patient's own blood, calcium lactate tincture of ferric chloride, intramuscular injection of horse serum, blood transfusion of 400 cc of citrated blood on the morning of February 25, liver extract and careful dietetic supervision.

February 25 when the lobule of his ear was pricked for a blood platelet count the puncture wound bled freely for twenty-four hours. It is interesting to note here that previous punctures of his finger tips had given no trouble.

There was no improvement after the blood transfusion and the hemorrhage continued. The patient was then desensitized by being given two small intracutaneous doses of 0.1 and 0.2 cc of antivenin at half hour intervals because of the previous administration of horse serum. The second dose was followed by 10 cc of antivenin given subcutaneously on the inner surface of the thigh. The leg was then bandaged and an ice cap applied the reason for doing so being the hemorrhage and swelling of the forearms which followed the two small desensitizing doses. Within twenty-four hours all bleeding stopped, and he has made an uneventful recovery.

February 25, the day of transfusion, this case history was presented during a staff conference of the Gorgas Hospital. It was suggested that antivenin be used. It was stated that Dr. Herbert C. Clark, now director of the Gorgas Memorial Laboratory in Panama City, had successfully treated a case of purpura hemorrhagica with antivenin in October, 1928, at Quigua, Guatemala.¹ His case, like the one here presented, was of so severe a nature that the man was nearly exsanguinated and not expected to live another twenty-four hours, horse serum and other treatment being of no avail.

The antivenin used in the case under discussion is marketed by the H. K. Mulford Company. It is a purified and concentrated serum globulin obtained from the blood of horses that have been highly immunized against the venom of certain tropical American serpents of the genus *Bothrops*, especially that of the fer-de-lance (*B. atrox*).

We will omit a discussion of the various conceptions of the clotting of blood, however, it may be stated that it appears to be due to the coagulation of fibrinogen or prothrombin by a fibrin ferment in the presence of calcium salts. The disintegration of the leukocytes and the necessity of the platelets also influence it in some manner. There is, too, an antithrombin normally present which prevents under normal conditions activation of the prothrombin (theory of Howell).

It is possible that some toxic substance might be the causative factor of hemorrhage in this particular case. It does not seem plausible that the destruction of tissue in the field of operation could account for the production of a toxic serum protein which, entering the blood stream, would act directly or indirectly as a hemorrhage producing agent.

Knowing that the naropharynx contains at all times a great variety of bacteria, it seems more reasonable to ascribe the formation of a possible toxic substance in this case to them.

Laboratory observations of the urine and blood were negative previous to the first operation.

Blood examination, January 4, revealed hemoglobin 70 per cent red blood cells, 3,650,000 leukocytes, 6,700 coagulation time seven minutes. From this time there was a steady fall in hemoglobin and red blood cells until February 24 when the count was erythrocytes 2,000,000 leukocytes 20,000 hemoglobin 40 per cent. The platelet count was 40,000. The bleeding time (ear) was twenty-four hours, coagulation time two and a half minutes, neutrophils were 84 per cent. No abnormal cells other than those seen in a secondary anemia were noted. February 26 the antivenin was administered. March 5 hemoglobin was 60 per cent red blood cells 3,500,000, leukocytes 9,350. March 10, the platelets were 272,000, reticulated red corpuscles 16 per cent. March 17 red blood cells 4,290,000 hemoglobin 65 per cent white blood cells 8,500 neutrophils 76 per cent. At no time was blood found in the urine, a few hyaline casts and pus cells were occasionally found. The Wassermann reaction was negative. Tests for malaria were negative. The blood type was group I, Jansky.

CONCLUSIONS

Although we cannot account for the action of antivenin in this case it appears that it might be a valuable agent in the treatment of hemorrhagic disease.

In giving the serum, it is necessary only to observe the same precautions as in giving any biologic remedy whose basis is horse serum.

MASTOIDITIS AND LATERAL SINUS THROMBOSIS IN AN INFANT

LOUIS H. SEGAR, M.D.

AND

WALTER STOEFLER, M.D.

INDIANAPOLIS

That mastoiditis may occur at an early age without evidence of middle ear involvement has been recognized by numerous observers.¹ Of thirty-five cases of mastoiditis in children, Steinsleger² encountered nine in the range of ages from 7 weeks to 23 months. Seven of these nine cases, or 77 per cent, showed no perforation of the tympanic membrane previous to operation. Grulee³ states that sinus thrombosis in the new-born is due either to a general infection in the blood stream or to direct extension from the ear, and that it is practically impossible to differentiate it from meningitis when symptoms are present.

The following case is an example of the tender age at which these conditions may be found and of the insidious manner in which they may develop.

REPORT OF CASE

The parents had one other child, aged 6 years, in excellent health. There was no history of familial diseases. The patient, a girl, was born Sept. 22, 1929. Her birth weight

was 6¼ pounds (2835 Gm) Delivery was normal A slight upper respiratory infection occurred about one week prior to the last illness This lasted a few days only and was recalled with difficulty by the mother November 22 when the patient was about 8 weeks old she had been restless and vomited The family physician found a slight elevation in temperature The following day the physician was again called because of restlessness No cause for the infant's distress and fever could be found The baby was brought to the hospital on the fourth day of the illness at which time the rectal temperature was 104.6 F The anterior fontanel was soft and not bulging, there was no rigidity of the neck The nose and ears showed no evidence of inflammation The chest abdomen and extremities were normal Knee jerks were elicited, and the pupils were equally contracted and did not react to bright light The urine showed nothing abnormal A blood examination showed hemoglobin, 63 per cent red blood cells, 3,250,000, white blood cells 32,500 with 53 per cent polymorphonuclear cells, 17 per cent small lymphocytes and 9 per cent large lymphocytes Metamyelocytes were 21 per cent A roentgenogram of the chest showed signs of a pneumonitis

During the preceding twenty-four hours the baby had been nursing fairly well The temperature remained around 104 F Both ear drums were of a normal glistening gray with normal light reflex and normal landmarks There were no areas of tenderness behind the ears There was, however, a beginning tendency to incline the head toward the right shoulder but no appreciable resistance was encountered on turning the head in various positions and anterior flexion of the head was well tolerated

Lumbar puncture was done and 12 cc of turbid fluid under increased pressure was withdrawn Before the lumbar puncture needle was removed 10 cc of antimeningococcic serum was introduced into the spinal subarachnoid region Examination of the spinal fluid revealed 9,200 cells with from 90 to 95 per cent polymorphonuclear cells, a direct smear showed no organisms We believed we were dealing with a meningitis and vigorous treatment consisting of spinal drainage and introduction of serum was instituted The patient did not improve The temperature became swinging in character and frequent attacks of cynosis occurred Marked restlessness required morphine Generalized rigidity and a beginning protrusion of the right eyeball appeared together with a diminishing amount of fluid from the spinal subarachnoid region A block at the base of the brain was considered probable and the right ventricle was tapped Clear fluid was obtained with an occasional flake of fibrin A report now on the culture of the spinal fluid read 'gram-positive staphylococcus probably a contamination' Later specimens of spinal fluid were found to contain a similar staphylococcus Because of the exophthalmos which had become more pronounced a cavernous sinus thrombosis was considered The baby now was moribund Convulsions had occurred She died six days after admission to the hospital and ten days after the onset of the illness

A bacteriologic study of the spinal fluid showed a gram-positive staphylococcus which presented partial hemolysis of a brown type and produced a very pale cream pigment

A partial autopsy by Dr H W Banks pathologist at the Methodist Hospital showed that the right eye was protruding and gave a spongy sensation on pressure The right pupil was about 2 mm in diameter and the left one about 3 mm The nose and ears were normal

The brain appeared to be blanched and edematous The convolutions were soft jelly-like extremely broad and shallow Pus poured out around the base of the brain where there was also yellow opaque fibrinous and semifluid material particularly around the emergence of the cranial nerves This occurred patchily and not uniformly over the base The cerebellum was edematous but no areas of hemorrhage or exudates were seen on its surface A mass of delicate fibrin threads extended over the lateral surfaces of the brain stem and cord around the foramen magnum producing a matted effect which closed off the cranial zone from the cavity of the spinal column The right lateral sinus was completely occluded and filled with a friable ivory pink clot that was evidently old and was adherent to the walls of the sinus As

the incision in the sinus was continued around the ridge of the sphenoid to the sellar turcica, there exuded a profuse creamy, yellow pus Pressure on this region caused pus to exude from along the area of the optic tract as it entered the orbit and pressure on the eye caused about 10 cc of thick pus to exude from the tract the eye receding to its normal position

The right mastoid cells were filled with a creamy, straw-colored pus The middle ear contained some thin watery fluid The drum was intact Cultures taken from the right mastoid, the right lateral sinus and the brain showed a staphylococcus similar to the organism grown from the spinal fluid

COMMENT

Mastoiditis in children is considered less dangerous than in adults and the urgency for surgical intervention less immediate As explained by Jackson and Coates,⁴ the bony cortex in a child is thin and the direction of the inflammation is usually external, causing carious erosion of the cortex and consequent escape of pus under pressure Occasionally, as this case illustrates, the mastoid infection extends into the intracranial cavity, probably along the free communication between the lymphatic and blood vessels of the middle ear and mastoid and the interior of the skull, provided by the ununited petrosquamous suture Because of this relationship, children frequently develop an otitic meningitis or other intracranial complication without evidence that an intral lesion is present

The most important element in this infant's course was the normal appearance of the right ear drum in the presence of a mastoiditis There must have been pus under pressure in the mastoid on the third or fourth day of the illness as the first specimen of spinal fluid obtained on the fifth day contained a large amount of pus evidence that the sinus thrombosis had formed some time previously and that the infection had spread to the meninges It is probable that the mastoid infection was present on the first day of the illness the staphylococcus having been implanted there at the time of the respiratory infection one week previous to the onset of the last illness Any departure from the normal appearance of the tympanic membrane would have been in this patient, the only clue to the existing pathologic condition It seems doubtful that a mastoid operation and ligation of the internal jugular vein on the day of admission would have changed the outcome Nevertheless, that procedure would have been indicated had any clue to the mastoid infection been discovered

The Structure of Neuroglia—The study of gliomatous tumors has been considerably advanced in recent years by the development and perfection of neuroglial staining methods The credit for this should be given to the Spanish school of neurohistologists notably Cajal and del Rio Hortega The methods of using gold and silver solutions or the former and the technique of silver carbonate staining with all its variations of the latter have brought to light many details of importance in the furtherance of knowledge of the structure of neuroglia To Cajal and his school is due much of the present knowledge of the histogenesis and structure of the astrocytic neuroglia, while del Rio Hortega has demonstrated clearly the histogenesis morphology and pathologic variations not only of the oligodendroglia but also of the other constituent of the third element the microglia or mesoglia These studies have clarified remarkably the knowledge of the normal structure of the neuroglia and mesoglia In so doing they have made clearer the nature of gliomas—Alperin B I. Origin and Development of Giant Cells in Gliomas Arch Neurol & Psychiat 25 281 (Feb) 1931

Clinical Notes, Suggestions and New Instruments

PRIMARY SARCOMA OF THE GALLBLADDER

ALEXANDER BRUNSCWIG MD CHICAGO

Primary sarcoma of the gallbladder is rare. Kaufmann¹ states that there are only thirteen cases on record. Landsteiner,² in 1904, was the first to summarize the literature on the subject and to that date was able to collect only six alleged cases

Fig 1—Section from primary sarcoma of the gallbladder showing rather densely packed moderate sized spindle cells slightly reduced from a photomicrograph with a magnification of 320 diameters

Three of these, he stated could not be definitely considered primary sarcomas of the gallbladder and in the other three the diagnosis was not finally accepted by him because the original descriptions were not available. Landsteiner's own case was a myosarcoma. At a later date he described another gallbladder exhibiting a spindle cell sarcoma and a squamous cell carcinoma.³ Bayer⁴ reported a case of myxochondro-osteosarcoma with adenomatous hyperplasia of Luschka's ducts. Parlavocchio,⁵ Hotes,⁶ Bayer,⁴ Griffon and Segal,⁷ Iwasaki,⁸ and Jaffe⁹ have each recorded a case of spindle cell sarcoma of the gallbladder in some of these, giant cells were a prominent feature. Carson and Smith¹⁰ observed a case of round cell sarcoma. Wieting and Hamdi¹¹ reported a case of melanoblastoma, and Becker¹² described a case of "endothelioma" (sarcoma?) of the gallbladder.

REPORT OF CASE

B. C., a small white woman, aged 55, entered the University of Chicago Clinics May 23, 1930, complaining of a pain in the entire right side of the abdomen of two months' duration. This was described as a dull "gas pain" and was never very severe. The pain was relieved by lying flat on the back and aggravated on standing. There was no jaundice, nausea, vomiting or constipation. The patient had lost 15 pounds (7 Kg) in the previous eight weeks and general weakness was rapidly increas-

ing. Her appetite, usually good, had become very poor during this period. Past personal and family histories were irrelevant.

The salient feature on physical examination was a large smooth tumor in the right upper quadrant and upper portion of the right lower quadrant of the abdomen. By palpation this was found to be caused by a nodular, firm tumor mass that extended from three fingerbreadths below the costal margin to the level of the right anterior superior iliac spine, medially it extended to the midline and laterally into the right flank. The liver edge could be palpated above the tumor. The mass moved with respirations and could be moved slightly by manipulation. It was not tender. Bimanual examination revealed that this tumor was not connected with the uterus or adnexa. Routine laboratory examinations were negative.

After intravenous injection of tetrathalam sodium (N. N. R.) there was nonvisualization of the gallbladder. Barium fluoroscopy of the stomach and duodenum showed a displacement of these structures to the left by the tumor mass, a barium enema showed the hepatic flexure of the colon to be displaced downward. Films of the kidney, ureter and bladder showed normal kidney shadows and no stones.

Exploratory laparotomy was performed by Dr. L. R. Dragstedt June 4. A right rectus incision was made and a small amount of colorless fluid escaped when the peritoneum was incised. A large hard tumor mass was found in the right upper quadrant primary in the right lateral wall of the gallbladder and extending into the right lobe of the liver. The gallbladder was enormously dilated, being about four times the normal size. About 50 cc of colorless fluid was aspirated from the distended gallbladder. No stones were palpated in the bile passages. A small portion of the tumor mass was excised from the gallbladder wall for microscopic examination and the abdomen closed.

The patient was discharged from the hospital, June 24. Her general condition was fair. Marked weakness persisted and it was thought the tumor mass had increased slightly in size.

Fig 2—Section from primary sarcoma of the gallbladder showing area of round cells and two large tumor giant cells slightly reduced from a photomicrograph with a magnification of 625 diameters

Because of increased abdominal pain, further emaciation and weakness, the patient was readmitted to the hospital, July 10. The tumor mass had markedly increased in size, filling almost the entire abdomen and forming a smooth, firm, fixed protrusion. She was discharged again, July 29, temporarily relieved from pain, and several days later word was received that she had died. Necropsy was not obtained.

PATHOLOGIC STUDY

Sections of the fragment of tumor removed at operation showed areas of moderate sized spindle shaped cells with oval

and rounded finely stippled nuclei. Between these cells were fine collagenic fibrils. Elsewhere there were dense strands of collagenic tissue separating small groups and strands of elongated spindle cells many of which were here indistinguishable from normal fibroblasts. There were regions in which round cells were predominant; these had a small amount of cytoplasm and moderate sized round or oval nuclei. A number of large multinucleated tumor cells were also present (giant cells). Numerous mitotic figures were seen among the round and spindle shaped cells.

The diagnosis was spindle cell sarcoma (with areas of round cells) of the gallbladder.

COMMENT

The rarity of primary sarcoma of the gallbladder may be more apparent than real, for many large tumor masses arising in the gallbladder, and found on exploration to be inoperable have no doubt gone without biopsy, the gross diagnosis of carcinoma being made. An analysis of the histories of the reported cases fails to disclose a clinical syndrome that may afford a basis for preoperative diagnosis of primary sarcoma of the gallbladder.

Of the thirteen cases referred to by Kaufmann, ten also exhibited cholelithiasis. In the case I have reported, as stated cholelithiasis was not present as far as could be determined at operation.

SHOE-DYE POISONING REPORT OF A CASE IN AN
EIGHT MONTHS OLD INFANT*

SAMUEL J. LEVIN, M.D., DETROIT

Shoe dye poisoning is relatively uncommon in children. Riviere¹ reported eleven cases of cyanosis in children 1½ to 10 years of age following the dyeing of shoes with a dye containing aniline. Muehlberger² reported two cases in children of 3½ and 6 years of age. Ullmann³ has called attention to the fact that children are especially susceptible to shoe-dye poisoning. Recently I reported a case of shoe dye poisoning in a child of 2 years, at that time the youngest patient in the American literature.⁴ The following case in an 8 months old infant is I believe, the youngest reported case of this interesting condition.

D. C., a girl aged 8 months white was admitted to the Children's Hospital Sept 3 1928 because of fainting and turning blue. She had had a full term, normal delivery with no cyanosis or convulsions. She had been breast fed for six months and was given a normal diet at the time of observation. She had always been perfectly well; she had had no similar attacks, convulsions or fainting spells.

Her parents were both well, with no history of epilepsy, allergy, tuberculosis or syphilis.

At 11 30 a. m., September 3 the child suddenly fell over backward in her highchair and five minutes later became unconscious. It was noted that she was then getting darker and she was immediately brought to the Children's Hospital.

On entering the patient's room one was immediately struck by a strong sweetish chemical odor. The infant was lying quietly in bed semicomatose but easily aroused. There was no odor of acetone on the breath. She was well developed and well nourished. The skin and lips had a peculiar cyanotic somewhat grayish blue color. The tongue was clear, the mucous membranes were a dusky bluish color. The tonsils and the pharynx were normal. There were no enlarged glands in the neck. The chest was of normal size and shape with equal expansion on the two sides and a normal resonance throughout. The breath sounds were clear; there were no rales. The heart was not enlarged and had a rate of 110; the heart sounds were normal; there were no murmurs. There were no masses and there was no rigidity or tenderness in the abdomen. The

bones and joints were normal. An examination of the nervous system revealed no neck rigidity, Kernig's or Brudzinski's sign. The reflexes were normal. A laboratory report of the blood showed hemoglobin 60 per cent, red blood count, 4,250,000 white blood cells 17,500, polymorphonuclears, 72 per cent. The temperature was 99.6 F. The urine was negative for albumin, sugar, acetone and urobilinogen.

The shoes of this infant which had just been removed, exuded the same peculiar odor that was noticed on entering the room. The canvas uppers had apparently been painted with a black dye, being still moist. The mother subsequently said that because the white canvas uppers were soiled she had dyed them black that morning and after waiting one hour had put them on the baby. The symptoms appeared after the shoes were worn only one hour.

Venous blood was withdrawn for examination. It was dark brown and did not become redder when shaken up with air. Spectroscopic examination showed a faint but typical methemoglobin band. The infant was treated with fresh air and oxygen and was apparently normal in twenty-four hours.

The solvents used in shoe dyes, either aniline or nitrobenzene have each been said to produce methemoglobinemia. In the cases reported in infants in which cyanosis followed the wearing of recently marked clothing aniline⁵ was isolated from the stamping ink in one series of cases and nitrobenzene in another.⁶ Methemoglobin was reported in the blood of the infants of both series by spectroscopic examination.

Muehlberger² in 1925, analyzing the forty eight cases of shoe dye poisoning reported up to that time in the American and European literature found that in the twenty-five American cases nitrobenzene was the chief toxic agent. He found that aniline was the chief toxic agent in the European cases reported.

In the ten cases which he reported at that time Muehlberger found that six were due to aniline, these being the first to be reported in this country. Pateh⁷ has since reported three more cases due to aniline.

It is now well known that absorption of aniline and nitrobenzene occurs through the skin with resultant symptoms like those found in shoe-dye poisoning. The chief manifestations are weakness, vertigo, somnolence, digestive disorders, headaches and cyanosis. The blood is dark, chocolate brown almost black.

Both aniline and nitrobenzene are extremely toxic. For this reason a number of manufacturers of shoe dye have used other supposedly less toxic solvents. The solvent present in the dye used in this case was 20 per cent orthotoluidine. In the report⁸ of a series of experiments which he conducted for the manufacturer of this shoe dye Muehlberger found 30 per cent orthotoluidine to be much less toxic than aniline. Rabbits developed only slight cyanosis when the substance was applied to the shaved abdominal surface. He subsequently dyed the shoes of six young adults who continued to wear the shoes for a period of from ten to fifteen hours after the application of the dye. In no case were there any noticeable symptoms of poisoning. Muehlberger concluded that for the average person a shoe dye containing 30 per cent orthotoluidine as a solvent is nontoxic.

COMMENT

Although 30 per cent orthotoluidine is apparently nontoxic for adults as a solvent for shoe dye severe symptoms were produced within an hour in an infant despite the use of a dye containing only 20 per cent of this substance. It may be reasonable to assume that the wearing of freshly dyed shoes remains a menace to infants.

CONCLUSIONS

1. A case of shoe dye poisoning in an 8 months old infant was observed. This is believed to be the youngest patient in the literature.

2. Despite the use of orthotoluidine as a solvent in this shoe dye a 20 per cent solution is apparently as toxic for infants as the aniline or nitrobenzene solvents formerly used.

THE COSTS OF MEDICAL EDUCATION

STUDENTS' EXPENDITURES *

R. G. LELAND, M.D.

Assistant Director, Bureau of Health and Public Instruction
American Medical Association

CHICAGO

It was inevitable that during the centuries while medicine was becoming integrated from meaningless bits of folk-ways, mysterious superstitions and primitive incantations into an orderly array of logical demonstrable truths, little should be recorded as to the cost of obtaining the information necessary to qualify one as a physician. Moreover, there is consistency in the finding that search for and interpretation of facts

training thus gained. To be sure, an individual trained in the thinking and investigating process should continue his education throughout life, but his actual college days are usually limited, to a degree, by the amount of time and money he feels he can invest and the readiness with which he can later adjust himself with his new equipment.

Were it possible to assemble data on the cost of medical education, from the time when Democedes founded the first medical school in Athens in 522 B. C. to the present, some interesting and doubtless valuable ratios might be found. Cost must of necessity increase with the expansion of medical education requirements. On the other hand, if students are to be expected to bear the increasing cost of medical education there is danger that the profession may become limited to the sons of the well-to-do.

Information for this study of the cost of medical education was drawn from every geographic subdivision

bearing on vital processes have been uppermost in the minds of the great teachers and investigators.

There is reason to hope that those qualities which characterized our medical ancestors as indomitable searchers for truths may forever be perpetuated. But in a world of increasing social and economic complexities it is no longer possible to disregard cost. Honesty of purpose and integrity of action will always be high values in character, but there must be a limit to which any educational process should be carried for the individual who must later seek his livelihood from the

of the United States, medical schools located in small cities and large metropolitan areas, state and non-state operated universities, long established and of more recent organization, and universities for both white and Negro students.

The expense data cover only the four years of required medical work. The cost of premedical training was omitted, since a measure of such expenditures would tend to be quite arbitrary. Preliminary college preparation is pursued in such a variety of schools and colleges and the range of work taken and time spent is so variable that it was thought best not to include any preliminary college work. Likewise, the cost of postgraduate and intern training has been omitted. Although the cost of postgraduate work may closely parallel

* This discussion of the cost of medical education is limited to the amounts paid by the student toward a medical education and does not include the cost to either medical schools or hospitals in providing facilities for a medical education. All references to the cost of medical education in this article must be understood to carry this limitation.

undergraduate education in many respects, postgraduate study does not apply to all students and it may extend over widely varying lengths of time. The intern, in many instances, is in reality practicing medicine under direction, although not always licensed, and he usually receives compensation which largely or completely covers any expense.

Early in 1929, forty medical schools located in the several geographic subdivisions of the United States approved of the plan to study one phase of the cost of medical education by means of students' expense books and offered to place these books in the hands of all medical students who would volunteer to keep the record. They also offered to supervise the recording of data and to maintain, as well as possible, through a member of the faculty, an interest in the project.

In nearly every instance the dean of the medical school voiced his doubt that all medical students would cooperate and, therefore, books were furnished only to

in other instances the returns were disappointing. Six schools failed to return any expense books. The total number of expense books which were found complete and which showed a degree of accuracy necessary for inclusion in the study was 1,253. This number, although representing a precariously small percentage for a detailed statistical study, is nevertheless sufficient from which to derive some significant hints as to the trend of the costs of medical education.

With a relatively small number of returns it becomes more and more difficult to arrive at as accurate deductions as could be made had the percentage approached more nearly 100. However, an attempt has been made to point out a few items of interest, as follows:

1 The variation, if any, in the cost of medical education to students as to the class year in the several geographic subdivisions of the United States.

2 The apparent cost of each of the several major expense items which contribute to the cost of the medical education

approximately 70 per cent of the school enrolment. Altogether, 7,200 expense books were sent to forty medical schools, having an enrolment for 1929 of 10,947 students. In a few instances additional books were sent on request of the dean. There was no direct contact between the American Medical Association headquarters and the students; the presentation of the subject and all subsequent follow-up contact to insure the largest number of returns and the greatest possible accuracy were through the dean or a member of the faculty of the student's own school. It is impossible, therefore, to make any statement or explanation concerning the number of returns credited to each school.

The percentage of books itemized throughout the year and returned from some schools was satisfactory,

3 The variation in the cost of each of the several major expense items according to class periods.

4 The distribution by expense intervals according to class periods and geographic subdivisions.

5 The distribution of the major expense items and magnitude groups according to the fractional percentage of the total cost.

These items do not represent the limit of inquiries for which an answer might be sought in the assembled data, but for general information, the five that have been outlined seem adequate. In all statistical procedures the probable error becomes larger the smaller the percentage of possible returns available, and therefore any conclusions drawn from the present study must be made very guardedly. Nevertheless, an effort has been made to present faithfully the expense data actually recorded.

and reported by 1 161 medical students for the college year 1929 and 1930. Neither the medical profession, the statistician, nor the public should be too exacting or critical of the apparent conclusions.

Examination of these reports indicates that, of the 1,253 students who returned itemized expense books, 19 were married and 73 were living at home. Obviously, the demands on the married students differ sufficiently from those made on the single students to cause these reports to be excluded from the tabulations. Because of the reduction in board room laundry and a number of other miscellaneous items it would be not only unfair but also statistically dishonest to include in the study the expenses of those living at home. There-

Howard University School of Medicine, Washington D. C., to \$1 342 64 for Jefferson Medical College, Philadelphia. Based on the percentage of enrolment, however, the returns of other schools should be considered in this connection, namely, Alabama School of Medicine, Colorado School of Medicine, Emory University School of Medicine, the University of Georgia Medical Department, North Carolina School of Medicine, Pittsburgh School of Medicine, Utah School of Medicine, and Yale University School of Medicine. Although the total number of reports returned from these schools was smaller than for some they represent a higher percentage of the school's enrolment and therefore may be accepted more readily as indicative of actual cost in

fore, the figures shown in tables 2, 3, 4, 5, 6 and 7 are for unmarried students living away from home. This number totals 1,161 (table 1).

The number of returns for this group (unmarried and not living at home), based on each college enrolment, varied from 0.4 per cent to 43.7 per cent. The number of returns and the enrolment according to the college year and the total for each school, is found in table 2.

The number of reports from several schools was so small that the average, either for the total amount expended for the year or for the expense for each class year, cannot be accepted as statistically dependable, it should be used simply as an interesting trend. In the case of seven schools, however, each of which returned more than fifty reports the results call for more than passing notice. The total average expense to students recorded from these schools varies from \$902.16 for

these institutions. The average expense of these eight schools varies from \$811.63 for the University of Georgia Medical Department to \$1,446.63 for Yale University School of Medicine. It would appear, therefore, that the low average annual student expense for a single medical school is found among the South Atlantic states although the Pacific and Mountain states are in the lowest range and the high average lies between the New England and Middle Atlantic states. An average taken by class periods seems to indicate that the amount expended by sophomores is lowest, \$1,114.58, whereas seniors seem to have the heaviest expenses, \$1,242.76. This difference is not as great as might be expected.

Except in one or two instances the number of returns according to class periods is altogether too small to make any safe or accurate comparison between schools or geographic subdivisions. The averages therefore shown in table 3 must be accepted as indic-

tive of the experiences of only as many as are represented by the returns received

The annual cost of each of the several major expense items that contribute to the cost of medical education shows in some instances a fairly wide variation (table 4)

That portion of the student's expense paid for tuition and fees is beyond his control once the selection of a medical school has been made. There is,

Chart 1—Graphic representation of 1161 expense reports according to the number in each magnitude group or expense interval

however, a wide choice of schools as far as tuition and fees are concerned. A number of factors seem to operate in the great diversity of this expense item. There are several schools that offer only the first two years of medical training. The tuition and fees in these schools varies from \$50 to \$410 a year. Among the schools conducting a full medical course the annual charge for tuition and fees extends from \$66 to \$610. Twenty-seven universities, mostly state institutions charge an additional fee for students who are non-resident in the state. These nonresident charges vary from \$10 a term to \$300 a year. Thirteen of the universities in the present study have additional charges for nonresidents.

Among the reports returned in this study 172 were found to be from nonresident students of the following ten medical schools (the number of nonresident students is given after each school)

- University of Arkansas School of Medicine 1
- University of Colorado School of Medicine 8
- University of Indiana School of Medicine 1
- University of Michigan Medical School 66
- University of Missouri School of Medicine 2
- University of Nebraska School of Medicine 12
- University of Oregon Medical School 2
- University of Vermont College of Medicine 14
- University of Virginia Department of Medicine 64
- University of Wisconsin Medical School, 2

The average annual cost of tuition and fees in the medical schools enumerated will not bear a parallel comparison with the remaining averages shown in table 4 under tuition and fees since the averages in these ten schools is increased by the extra charges paid by the nonresident students.

Making necessary corrections for the nonresident students' fees it is found that the lowest fees of the medical schools included in this study are those paid by students in the University of Texas School of Medicine and the highest amounts are paid at Johns Hopkins University School of Medicine.

The average of the amount expended for medical books, instruments, medical journals, and the like, has a range which lies between \$66.57 found as an average for fourteen students at the University of North Carolina School of Medicine, and \$188.83 the average for sixteen students at the University of Alabama School of Medicine. Sixteen of the thirty-four schools reporting showed an average expenditure for this item of more than \$100, while eighteen showed an expenditure of less than \$100.

Board and room was considered jointly, since the arrangement in many places is to pay for board and room in a single sum. Many of the students, therefore did not separate the amounts paid for each item and it

H	2.5 PER CENT
G	5.3 PER CENT

C	11.8 PER CENT
B	25.7 PER CENT
A	33.4 PER CENT

Chart 2—Average annual total cost distributed according to percentage paid for each major expense group. Major expense groups: A board and room 1161 reports average \$388.54; B tuition and fees 1161 reports average \$298.60; C clothing and laundry 1159 reports average \$137.30; D medical books, journals, instruments, etc. 1159 reports average \$103.68; E recreation 1119 reports average \$77.63; F travel 1119 reports average \$70.99; G miscellaneous 1148 reports average \$62.22; H insurance and interest 443 reports average \$77.45.

was possible to consider them only as a joint expense. The expenditure for this item shows a low average of \$271.75 from the University of Illinois College of Medicine and a high average of \$569.45 representing thirty-two reports from the Harvard University Medical School. Again the low average for Illinois is

not dependable, since only two reports were received. Clothing and laundry were combined for the same reason, and this item shows a variation of from \$61.68 for the University of Missouri School of Medicine to \$178.61 found as the average of forty-seven reports from Tulane University of Louisiana School of Medicine. The \$61.68 represents an expenditure of only three students which cannot be accepted as altogether representative. One other lower average of \$50.46 was reported by one student of the University of Arkansas School of Medicine.

person lending the money are legitimate inclusions, since the principal sum makes possible the pursuit of the educational courses. Presumably the 718 students who did not report expenditures for insurance and interest either earned the money or received it as a gift. The expenditure for this item varied from \$29.83, the average reported by three students from the University of Missouri School of Medicine, to \$114.58, the average of seventeen reports from the Tulane University of Louisiana School of Medicine. It will be seen from the table that two lower expenditures, one of \$9.44 and

The item of travel introduced the unknown factors of the distance of the student's home from the university and the number of trips made to and from the university during the year. These variables should be borne in mind in considering the figures, which show that the amounts spent vary from an average of \$24.70 for three students at the University of Missouri School of Medicine to \$140.14 reported as an average for five students from Dartmouth Medical School.

It should be noted that, of the 1,161 students, only 443 have made reports on insurance and interest. This item is justifiably included on the ground that the interest on borrowed money to finance an education and the premiums on life insurance carried to protect the

one of \$13.50, were reported by one student in each of two schools and a high expenditure of \$174 was reported by one student in another school. These, however, are individual experiences and cannot be used as representative.

The average amount paid by students for recreation was found to vary from the low figure of \$20.86, reported by ten students from Woman's Medical College of Pennsylvania, to the high amount of \$153.53 shown by five reports from Dartmouth Medical School. Miscellaneous expenses varied from \$26.36, shown as the average of ninety-two students at Howard University School of Medicine to \$111.61, reported as an average of five students at Dartmouth Medical School.

Two reports from the University of Illinois College of Medicine show a low average of \$23 43, and two reports from Johns Hopkins University School of Medicine indicate a high average of \$130 37, but these are too close to individual experiences to be accepted as representative.

It will be noted that the average total cost to students reaches the high amount of \$1,716 75 shown by five reports from Dartmouth Medical School, with Harvard University Medical School a close second showing an average of \$1,621 75, based on thirty-two reports. The

The average of \$437 12 reported from Dartmouth Medical School was by two students only. The detailed figures for all these major items according to school and year are given in table 4.

An examination of the average annual expense for each major item according to class periods shows that tuition and fees seem to be lowest for seniors and highest for freshmen. It appears that sophomores pay least and freshmen most for medical books, journals and instruments. There is but a slight variation in the cost of board and room, however, sophomores seem to

low average total of \$693 81 cannot be used since this represents but one report and furthermore since the lowest total expense reported was \$424 99 from the University of Wisconsin Medical School.

Although the work of not only lectures and laboratory but also demonstration and clinic has become increasingly more exacting for the student it is evident that about half of them find time through either choice or necessity for some kind of grunt work. The earnings of 518 students shows an average of \$283 48 for 1929-1930. The low average was reported by eight students from Emory University School of Medicine, \$29 81. Seven students from the University of Oregon Medical School reported an average of \$427 12

spend least and seniors most for this item. The freshman gets by with the least expense for clothing and laundry while this item draws heaviest on seniors. The increase here seems to be a gradual fairly even step up during the four class periods. Possibly a gradual growth in social prestige may have an influence. The sophomores seem to travel slightly less or at least their average expense is slightly under all other classes. The highest average travel expense seems to fall on seniors. The amount paid for interest and insurance is lowest for freshmen and highest for seniors. Theoretically at least, this is as this item might be expected to stand. Juniors spend least and seniors most for recreation. The miscellaneous items are surprisingly closely divided

however the least is expended by juniors and the most by seniors in this subdivision.

The total annual expense then, seems to fall lightest on sophomores and heaviest on seniors. It is exceedingly interesting to note that earnings show a gradual but steady increase from the low average for the freshman year to the high average for the senior year (table 5).

are more nearly represented by the bracket \$600 to \$1,600 inclusive. The median for this smaller group ranging from \$600 to \$1,600 inclusive is \$1,107.27, and the average for this group is \$1,125 (table 6 and chart 1).

The geographic distribution indicates that student expenses are highest in the medical schools of the New England and Middle Atlantic states. The reported

Fourth year	144	36,097.62	\$250.68	144	13,083.73	\$91.14	144	58,908.74	\$409.09	144	24,422.67	\$169.60	131	13,481.01	\$102.91
Unidentified	50	14,561.04	\$291.22	50	5,943.40	\$118.89	50	20,921.81	\$418.44	49	7,003.39	\$143.14	47	\$3,241.30	\$69.81
Total	1,161	\$346,669.64	\$298.60	1,159	\$122.48	\$10.68	1,161	\$4,019.92	\$388.54	1,159	\$1,013.41	\$113.30	1,119	\$1,013.41	\$113.30

The reports studied showed a wide range of expense intervals, from \$424.99 for one freshman to \$2,839.80 for one sophomore. Table 6 shows the distribution of the actual individual expenses by expense intervals or magnitude groups according to class periods and the geographic location of the school. The median for all reports is \$1,120.86, the average \$1,163.05. The table shows that the very low and exceedingly high amounts are relatively unusual. The total of these several items, therefore, distort the true median and average, which

expenditures for the medical schools of the Pacific and Mountain states appear to be lowest. The expense for the schools of the South Atlantic states closely approaches the western averages. The percentage of the average total expense that is paid for each major expense item is shown in table 7 and chart 2. Board and room call for 33.4 per cent of the total, a general average expense of \$388.54 annually. Tuition and fees represent 25.7 per cent of the total expense, averaging \$298.60. These two items, it will be seen, call for 59

per cent of the student's annual expense. No attempt has been made to ascertain whether expenditures were in any instance exorbitant or unnecessary. However, when it is found that 50 per cent of the students reporting are meeting their necessary expenses with approximately \$1,100 or less it becomes difficult to interpret the expenditures in the upper brackets as high as \$2,839, in terms of actual necessary college demands.

The results of one study, however, provide a few valuable figures that closely parallel the present investigation. These comparisons are given in table 8. The former study was made in 1920 by Dr. Irving S. Cutter and embodied data from eight medical schools. Figures from Dr. Cutter's study are given only in those instances in which his analysis and the present study approach the same classifications.

There may be merit to the argument that college training, to be of greatest value, should embody something more than the gathering of facts from classroom and laboratory. If this is true and if there is a social or extramural training that requires some financial outlay, it may be that some of the students whose expenses fall in the lower brackets are denying themselves a legitimate part of the potential college benefits.

There have been few studies on this subject and therefore one cannot make the comparisons one wishes.

It appears from this table that tuition and fees are the items that have increased most, more than 50 per cent. Books and instruments now cost about 50 per cent more than in 1920. On the other hand, board and room and clothing show a surprisingly slight rise and the expense for recreation has taken a decided decline.

All items for both studies cannot be shown and the schools studied in the two reports differ, but the average total expense for all the schools studied shows

an increase now of \$273.39 over 1920-1921. No attempt has been made to reconcile these figures with the change in value of the dollar over the past ten years.

schools averages slightly more than \$1,100. Tuition and fees and board and room call for 59 per cent of the average total expense. Costs seem to be highest in the schools of the New England and Middle Atlantic states.

SATURDAY, FEBRUARY 28, 1931

THE COSTS OF MEDICAL EDUCATION

Elsewhere in this issue appears a report by Dr R G Leland of an investigation into the costs of medical education. This investigation was stimulated by the Committee on the Costs of Medical Care and is one of several investigations undertaken by the American Medical Association at its own expense in order to supply facts relative to medical economics not heretofore available.

Many estimates have been ventured by various observers as to the amount of money spent by the average young man—or in many instances no doubt by his parents—in order to provide him with a medical education. The impression has been that the cost is approximately \$1,000 a year for tuition and maintenance. The investigation made by Dr Leland reveals the actual sum spent by the student in any year as \$1,100, this including tuition and fees, books and periodicals, board and room, clothing and laundry, and recreation. In 1920, by contrast, the amount was almost \$900. The figures submitted do not include the cost of premedical education or such expenses as may be incurred during the term of internship that is required by all colleges and most state licensing boards. Neither do the figures take into account the interest on the investment or the amount of money the young man might have earned were he in a gainful occupation rather than in a professional school. At the lowest possible estimate apparently, a medical education must cost at least \$5,000 and if all the factors are taken into account may cost in actual cash expended as much as \$10,000. If possible earnings and interest are added the cost may actually reach \$20,000. It is doubtful whether there is any other occupation in which men engage in which the cost of training is so great. Certainly there is no other vocation in which the time spent to reach efficiency is so extended. The gradual lengthening of the medical curriculum through the demands for premedical education, for internship and for special training, has prolonged the infancy of the

young man in medicine to almost thirty years. The human infant at best has the longest period of infancy of any living species. Whereas many animals are competent to take care of themselves and, indeed, to produce families one week after birth, the human infant is not competent to take care of himself until from eighteen to twenty years after birth. If he embarks on a professional vocation, the period is extended to thirty years. From the point of view of the biologist, it is doubtful whether this is a sound trend in human life. The persons most likely to produce progeny capable of raising the intellectual if not the physical standard of the race postpone their maturity beyond the age when biologists are convinced that optimal conditions exist for reproduction.

Beyond these biologic and sociological considerations are the economic factors. If the sum represented by the cost of a medical education were properly invested for a young man at the age of 20 years, he would have at 50 years an income capable of maintaining him in comfort for the rest of his life. Possibly the studies now being made on the incomes of physicians will indicate that the income of the physician at 50 years is seldom sufficient to maintain him in reasonable comfort for the remainder of his existence. Indeed, it is a question whether the average income of the physician represents a reasonable return on the cost of the education.

With these considerations in mind, it is interesting to turn to one of the latest promulgations on the subject of higher education. Mr Abraham Flexner, who has given much thought to medical education and who is no doubt to be credited considerably for the prevailing high standards, has recently summarized his views in a volume entitled "Universities American, English, German." The time is perhaps not yet propitious for such a summary in view of the fact that many of the changes in medical education for which Mr Flexner is largely responsible seem to be at this moment in a state of such agitation that even the most optimistic observer might be doubtful as to what the precipitate will be. Mr Flexner is, of course, more interested in maintaining high standards of teaching and research than in the education of physicians to take care of the majority of the people. Indeed, he conveys the impression that there is not a medical school in the country that really comes up to the standards he thinks necessary for a medical school. Mr Flexner is convinced that there can be no medical school worthy of the name without sufficient endowment to make its faculties entirely independent from other sources. One is inclined to the opinion that a further advance in the cost of medical education might well bring about the point of view that a sufficient endowment is necessary to make the students absolutely independent of any income from personal earnings or their parents if they are to complete the curriculum in a school of the

Flexner standard. The absurdity of the entire discussion becomes apparent when Mr. Flexner, in one of his sapient sentences, figuratively bites the hand that feeds him. "On the other hand, in England, as in America and the rest of the world, wealth may still triumph over reason; neither we nor they nor others have found effective means of putting the idle and stupid rich in their proper place."

The recent conference on medical education held under the auspices of the Council on Medical Education and Hospitals of the American Medical Association indicated that the problems of medical education are by no means settled. The curriculum still remains the subject of more or less confused discussion. The time spent by young men in professional schools is obviously too long, and it seems quite reasonable to propose that men sufficiently advanced in years to engage in professional study do not require a three or four months vacation but might well shorten their time by occupying at least eleven months of the year in study. It is questionable whether the cost of medical education can be greatly reduced, and certainly the demands on the student as shown by the figures presented by Dr. Leland are such that his actual earnings by outside work can hardly be counted on to be of much value. The presentation of facts in Dr. Leland's article is again proof of the necessity of more actual evidence in this field on which to base discussions rather than of any attempt to settle these problems by armchair philosophers and unpractical idealists.

STATISTICAL STUDIES OF DEAF CHILDREN

Shambaugh and his associates¹ have recently completed a comprehensive study of 5,348 children in institutions for the deaf. Similar studies have not been attempted before, although Newhart² and others have studied children in public schools for evidences of deafness. Shambaugh's study consists of an analysis of the history and a complete aural examination of each patient. Sixty-two per cent of the children were found to be congenitally deaf. More than half of the cases of acquired deafness occurred before the age of 3. Shambaugh declares that probably a large proportion of the group of acquired deafness are really congenital, since parents desire to escape the stigma of having given birth to deaf children and because deafness is often not definitely established until the age of 3. The statistics show that severe deafness in children is acquired in almost all cases before the age of 10.

Meningitis was responsible for almost one fifth of the cases of acquired deafness, while measles caused 83 per cent and scarlet fever and influenza each caused 7 per cent. There was an accompanying suppurative otitis media in many cases. The study revealed that hearing or vestibular responses were present in most cases in which there had been suppurative otitis media. The authors believe that suppurative otitis media, if it invades the inner ear, will destroy all vestiges of hearing and vestibular responses. They conclude that the deafness may result from a toxic neuritis developing independently of the otitis rather than from an extension of the suppurative process into the inner ear. They declare that tonsils and adenoids "can be responsible for a severe deafness only through an otitis media that has invaded the labyrinth—a negligible factor in this series."

Hereditary syphilis apparently causes but few cases of acquired deafness. Wassermann reactions were positive in only two of the 396 cases tested. A family history of deafness or of consanguinity was found in more than a third of the cases of congenital deafness. The common assumption that in congenital deafness the vestibule is not involved was disproved when it was shown that two thirds of this group gave diminished or absent vestibular responses. Vestibular responses were absent in both the congenital and the acquired groups in the same proportion whether partially or totally deaf. Three fifths of the entire group had a speech defect so pronounced that the untrained listener had difficulty in understanding the child.

While such a study may have many errors because data must be collected from whatever histories are available, the large number of cases should nullify gross errors. The great majority of cases of deafness requiring institutional care are apparently congenital. That heredity is an active factor in the production of congenital deafness is indicated by the large number of cases of deafness in the immediate family. Shambaugh declares that persons from families with congenital deafness should not bear offspring. Probably congenital deafness will continue to be prevalent as long as eugenic marriage is not practiced. In this study there were 232 patients whose parents were relations by blood, yet only 17 per cent gave a history of deafness in the family. It would seem from this result that intermarriage, even between distant relatives, tends to summate and bring out remote hereditary defects in hearing. Shambaugh's belief that a suppurative process of the inner ear must necessarily destroy completely hearing and vestibular responses requires confirmation. Careful studies of the inner ear in cases of severe deafness with a history of suppurative otitis media would do much to settle the point. The faithful use of measures now available for the treatment of the infectious diseases, especially meningitis and scarlet fever, might help much to lessen the incidence of acquired deafness.

LIMITATIONS OF BACTERIOPHAGE
THERAPY

The "d Herelle phenomenon" has been the subject of 2,000 published papers since it was first described in 1915 by Twort.¹ As yet but little agreement has been reached as to the mechanism of action of the bacteriophage and there is no reliable guide to the practical limitations of therapy by its use. The chief factor contributing to this uncertainty has been the lack of a dependable quantitative method. Last year, Dr A. P. Krueger² of the Rockefeller Institute, Princeton, N. J., devised a quantitative technic by means of which for the first time bacteriophage could be estimated with an accuracy of ± 3 per cent. Using this new technic, Drs Krueger and Northrop³ studied the kinetics of the bacterium-bacteriophage mixture. Their revolutionary results seem to prove that future theories must be developed along radically different lines from those suggested by any previous investigator and that future therapy must be limited to certain definite anatomic types of infection.

Drs Krueger and Northrop were unable to find the least evidence that the transmissible lysis of Twort is a living biologic entity. During the stages preceding explosive bacterial lysis there is no evidence that ordinary amounts of bacteriophage exert any physiologic or pathologic effects on the bacterium. It neither stimulates nor retards bacterial growth. Proliferation of the Twort lysis is intimately linked with bacterial multiplication. The bacteriophage is formed within the bacterial cell and diffuses outward at such a rate that extracellular concentration and intracellular concentration of bacteriophage maintain to each other a constant mathematical ratio. This is a type of distribution common to simple chemical substances but one hardly to be expected if the bacteriophage is a complex vital unit. When a certain critical ratio between bacterium and extracellular bacteriophage is attained, bacterial multiplication ceases and bacterial dissolution begins.

Krueger and Northrop have developed mathematical equations that accurately predict all the major events of this relationship including the rate of bacterial growth, the rate of bacteriophage formation, time of lysis, and concentration necessary for bacteriostasis. In their practical bearing the Krueger-Northrop equations mean that a certain critical concentration of extracellular bacteriophage is essential for bacteriolysis in about the same way that a critical environmental carbon dioxide concentration is necessary for death from carbon dioxide autoinflammation. This means that no therapeutic effects whatever are predictable for bacteriophage except under conditions in which local

extrabacterial bacteriophage concentration can be raised to and maintained at this critical level. This can be done either by direct introduction of massive doses of bacteriophage or by allowing free bacterial growth in the presence of smaller doses. Such a critical extrabacterial concentration could hardly be expected in any tissue in which extracellular bacteriophage is denatured, bound, removed or diluted by such factors as circulation, lymph flow or urinary secretion. Bacteriophage therapy, therefore, would be a predictable disappointment in erysipelas, furunculosis, pneumonia, pyelitis, cellulitis and bacteremia, and in cystitis except by concentrated irrigation. The use of this therapy would thus be practically limited to such closed organs as the intestine and to well encapsulated pus cavities. If bacteriophage should prove to be the therapy of choice in but one of these conditions, it would amply repay for the past fifteen years of false starts and clinical disappointments.

Current Comment

THERAPEUTIC POSSIBILITIES OF
GASTRIC MUCIN

The variegated manifestations of the common cold and its analogues include extensive mucous secretions and expectorations. Mucus is derived not only from the nasopharynx or other parts of the respiratory tract but also from the other mucous membranes. Mucus usually awakens memories of a thoroughly objectionable product of disordered membranes. Nevertheless it is mostly a blessing to the human economy. It catches and holds many objectionable invaders, it makes possible a more comfortable passage of otherwise irritating food masses along the many feet of the gastro-intestinal canal, it smooths over the roughened edges of injurious objects, such as glass and iron particles, that have found their way down the esophagus. The compensatory virtues of mucus are moreover not fully covered by the recital of such physical functions, for its components are distinctly antacid in character. Thus the gastric mucus aids in protecting the cells from digestive or 'erosive' damage by the acid that is poured into the lumen of the stomach when the gastric glands are active. Undue secretion of mucus in the stomach is responsible for lowering of the gastric acidity, just as proteus tend to 'bind' free hydrochloric acid. The actual capacity of mucus to produce such an effect has been verified by Fogelson¹ at the Northwestern University Medical School. Mucin prepared from hogs' stomachs was more potent than equivalent amounts of common protein foods such as gelatin meat and egg white. The use of the product in a few human patients with definite histories of ulcer and typical roentgenographic evidence of peptic ulcer was interesting. In addition to the customary bland diet an ounce of powdered mucin was added to each meal and about 1 Gm. of mucin in tablet form given

hourly. All these patients were relieved of subjective symptoms within three days of treatment. There was no recurrence of pain for many weeks. The history of the treatment of peptic ulcer with its stories of remissions under all manner of treatments is too familiar to warrant any undue enthusiasm about any novelty, however well authenticated. In any event, this research lends a little new dignity to a much despised physiologic substance.

DEFICIENCY OF VITAMIN AND TOXEMIA

The expression "toxemia" is drawn into service at present as an explanation for a variety of manifestations of disease for which no clearer interpretation is available. At one time or another several of the glands of the organism, such as the thyroids or adrenals, have been alleged to be connected in function with the destruction or detoxication of hypothetical "poisons," usually assumed to be endogenous in character. In the failure of the normal behavior of the glands the resulting disorder was quite naturally, though by no means always logically, attributed to a "toxemia." This sort of explanation has been applied to the appearance of neuritic symptoms in cases of deficiency of vitamin B. As Cowgill¹ has recently pointed out, the startling cures that occur following the administration of vitamins to so-called polyneuritic pigeons, in which nerve degeneration can be demonstrated so readily, can hardly be explained as due to sudden correction of the degenerative changes in nerves. This has led many investigators to favor the idea of toxemia. It has been suggested, he adds, that the toxins may be ingested with the food, developed from the materials in the alimentary tract, or be the result of a deranged tissue metabolism. One of the methods supposed to relieve such a condition consists in "washing out" the system by liberal intake of water and producing a vigorous diuresis. This process is sometimes accelerated by the parenteral administration of fluid. The plan has been put to the test in the laboratory of physiologic chemistry at Yale University by Cowgill and his collaborators in the case of animals deprived of their optimal intake of vitamin B by a selected regimen. When they were given large amounts of water by mouth it was found, contrary to what might be anticipated, that the time required for the appearance of the anorexia characteristic of a lack of this dietary essential was markedly shortened. Instead of being protected, the animals were invariably rendered more susceptible to the deficiency in the vitamin. Cowgill points out that this result is not in harmony with the hypothesis that the symptoms of a deficiency of vitamin B are essentially those of a toxemia. The urge to eat was restored by administration of mixtures of (undifferentiated) vitamin B. An explanation of the early symptoms when fluids are forced by mouth may be found in the possible removal by diuresis of vitamin still present in the body. If this is correct it may lead to a better therapy of infants suffering from anorexia and anhydremia. Cow-

gill suggests that one phase of the treatment which these infants often receive, namely, subcutaneous, intravenous and rectal administration of fluids, may actually be detrimental in that it washes vitamin B from an already partially depleted body. It seems logical, in the light of the experiments here reported, to combine the recognized and approved methods of treatment of such cases of marasmus with the administration of some potent source of vitamin B. Certainly sufficient evidence is at hand, he concludes, that trials of such therapy are warranted. In any event the vague assumption of an existing "toxemia" may no longer be entirely sufficient to the clinician.

MEDICAL BROADCAST FOR THE WEEK

American Medical Association Health Hints

The American Medical Association broadcasts at 10 a. m. Monday 10 45 on Tuesday, 9 15 on Thursday and 10 30 Saturday, over Station WBBM (770 kilocycles or 389.4 meters). The program for the week is as follows:

- March 2 The Sequel of Some Colds
- March 3 The Mental Grading of Children
- March 5 Some Facts About Yeast
- March 7 Practicing Health in Our Schools

Five Minute Health Talks may be heard over the Columbia Broadcasting System daily except Sundays and holidays from 12 to 12 05 p. m.

The program for the week is as follows:

- March 2 Man's Marvelous Machinery
- March 3 Hygiene
- March 4 Old Age
- March 5 Figures in American Medicine
- March 6 Sleep
- March 7 Sleep

Recently the number of stations on the Farm Community Network have been increased. The stations over which the noon talks may now be heard are as follows: WBBM Chicago, WCCO Minneapolis, WNAX Yankton S. D., KOIL Council Bluffs Iowa, WMT, Waterloo, Iowa, KSCJ, Sioux City,

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

ALABAMA

Personal—Edward A. Boyden, Ph.D., professor of anatomy, University of Alabama School of Medicine, has been appointed to a similar position at the University of Minnesota School of Medicine, succeeding Richard E. Scammon, Ph.D. Dr. Boyden will move to Minnesota, June 1.—Mr. W. T. Fales, director, bureau of vital and mortuary statistics, state department of health, has been appointed by the Rockefeller Foundation; it is reported, to cooperate with the Roumanian government in developing its vital statistics. Mr. Fales was to have sailed February 4.

ARKANSAS

Bills Introduced—H. 357 requires all practitioners of the healing art to respond to all calls for their services. If the patients are not able financially to pay for any service, physicians are to be allowed a reasonable fee, to be paid out of the county general fund. S. 317 proposes in effect, to exempt osteopaths from the provisions of the basic science law. S. 322 proposes to repeal the basic science law.

CALIFORNIA

New Student Hospital—The new Ernest V. Cowell Memorial Hospital of the University of California has recently been completed. It is five stories high and incorporates an outpatient dispensary, administrative offices, laboratories and hospital. The students indicate in writing the service desired and the records of the complete physical examination given to all students on matriculation are dispatched to the physician's office to which the patients are assigned. The two lower floors are devoted to administration, waiting and treatment rooms, laboratories and storage rooms. The three upper floors are for hospital purposes and have a capacity of 100 beds. There are eleven wards of four beds each. The fifth floor contains on the east end a suite for the resident physician, a ward and a sewing room, while the west end is devoted to surgery. The building is for sick students at the university; its objective being to show what can be accomplished by scientific preventive and curative medicine and to reduce absenteeism from classes because of illness. The Cowell Memorial Hospital was named in honor of an alumnus who willed a sum sufficient to pay for the greater part of the building. Dr. Robert T. Legge is the university physician. The professional staff consists of a medical director and twenty-eight physicians. During the fiscal year ended June 30, 1930, 70,824 dispensary treatments were given and 954 bed patients were confined to the hospital.

COLORADO

Society News—The recently organized Denver Urological Society elected Dr. Harry H. Wear, 915 Republic Building, Denver, secretary.

Bills Introduced—S. 341 and H. 149 propose to require that all pupils and teachers be immune to smallpox before they attend or teach school. This immunity may be evidenced by (1) having had smallpox, (2) having been successfully vaccinated within five years, or (3) having been vaccinated three times unsuccessfully. H. 75 proposes to require all hospitals, sanatoriums, maternity or lying-in institutions and other institutions for the care of the sick or injured to be licensed by the state board of health. H. 403 proposes to make it the duty of physicians, nurses, midwives or other persons who assist or are in charge at the birth of infants to instill into the eyes of infants within one hour after birth a prophylactic approved by the state board of health.

CONNECTICUT

Bills Introduced—H. 982 to amend the Pharmacy Practice Act, proposes to allow any person, firm or corporation holding a license from the commission of pharmacy to sell drugs in original packages as compounded by a licensed pharmacist to designate the place of sale as a "package drug store." H. 414 proposes to provide (1) that no private institution for the mentally deficient shall receive as a patient any person afflicted with tuberculosis or any other communicable disease or any patient from outside the state, (2) that the attendants in any such institution must have the training of practical nurses, and (3) that inspection of such institutions be made by the state at least once in three months. H. 654, to amend the dental practice act, proposes to add to the causes for which a license may be revoked (1) "the publication or circulation of fraudulent or misleading statements by a licensee, or his agents, concerning the licensee or his employees, or concerning the skill or method or technique of any person or operator, or concerning the employment of accessory agents such as anesthetics or drugs or materials by any person or operator," and (2) "the conviction of any crime involving moral turpitude." H. 979 proposes to grant a license to Ellery G. Peckham of Stamford to practice naturopathy. S. 212 proposes that any licensed nurse who lives outside the state or who practices nursing wholly without pay or material compensation shall register annually with the state department of health but shall not be required to pay an annual registration fee. S. 444 proposes to authorize the state to pay to any charitable institution, hospital or home for the aged not operated for profit or gain and not receiving state aid \$10 a week for each poor and indigent patient suffering from a chronic and incurable disease and treated in such hospital.

DELAWARE

Bill Introduced—H. 129 proposes to create a board of examiners of beauticians and to regulate the occupation of beauty culture.

FLORIDA

Sentenced to Penitentiary—Dr. Francis K. Armstrong, Fort Myers, was found guilty of manslaughter, Dec. 13, 1930 as the result of an illegal operation at his private hospital Oct. 13, 1930. According to the state board of medical examiners, Dr. Armstrong was denied a new trial and sentenced to serve ten years in the state penitentiary.

Personal—At the annual state public health conference, held in Jacksonville Dec. 8-10, 1930, a portrait of the late Dr. Joseph Y. Porter, Sr., first state health officer, was presented to the state board of health by his family. Dr. Joseph N. Fogarty, Daytona Beach, made the presentation address and Dr. H. Mason Smith, Tampa, president of the state board of health, the speech of acceptance.

GEORGIA

Personal—Dr. Frank Z. Story, Millen, has resigned as health commissioner of Jenkins County.—Dr. Owen F. Moran succeeded Dr. Lucius A. Bailey as health officer of Baldwin County recently.

Society News—Dr. Aubrey Edgar Boling, Jr., presented an illustrated lecture before the Fulton County Medical Society, February 5, on Cesarean Section Under Local and Spinal Anesthesia. and Drs. Roger W. Dickson and David H. Poer gave a clinical talk on "The Closed Method of Treatment of Acute Empyema." Dr. William C. Waters, Jr. spoke on "Auricular Fibrillation—Cases Treated with Quinidine Sulfate" before the society February 19 and Dr. Edgar Fincher, Jr. on "Indications for Laminectomy in Spinal Injuries."

The annual meeting of the Georgia Public Health Association was held January 15-16. Drs. Louis L. Williams of the U. S. Public Health Service and Thomas F. Abercrombie, state health commissioner, spoke on malaria prevention and on prophylactic state and national legislation respectively.

INDIANA

Bills Introduced—H. 405 proposes to regulate the practice of barbering. H. 361 proposes to regulate the practice of cosmetology.

IOWA

Bill Introduced—H. 259 proposes to authorize the issue without examination of licenses to practice dentistry to holders of certificates of the National Board of Dental Examiners.

KANSAS

Bill Introduced—H 524 proposes to authorize the boards of education in certain cities and the governing boards of rural high schools, community high schools and district schools to employ one or more nurses

KENTUCKY

Sentenced for Narcotic Violation—Dr Thomas B Helm, Paducah who was indicted in the United States District Court, Louisville, for violation of the Harrison Narcotic Act Nov. 17, 1930 pleaded guilty and was sentenced Nov. 18, 1930 to serve one year and one day in the United States Penitentiary at Atlanta

Personal—Dr J. W. Davis was elected January 16 to serve as health officer of Fayette County to fill the remaining two years of the unexpired term of Dr Rollin E. May, who resigned January 1.—Dr James S. Lock, Barbourville, has resigned as executive secretary of the Kentucky Tuberculosis Association after several years service

Society News—A symposium on the X rays was presented before the Jefferson County Medical Society, Louisville, January 5. Drs. Sydney E. Johnson, Henry C. Herrmann and Samuel A. Overstreet discussed diagnosis of bone diseases, pulmonary tuberculosis and peptic ulcer respectively, and Drs. David Y. Keith and Isaac T. Fugate roentgen therapy in tumors of the chest and diseases of the blood, respectively. Dr. Lawason Brown, Stram Lake, N. Y., addressed the society, January 19 on 'Diagnosis of Pulmonary Tuberculosis for the General Practitioner'. A symposium on heart disease was conducted before the society, February 2, at Louisville; the speakers were Drs. Woodford B. Troutman, Joseph C. Bell, Emmet F. Horne and Siegel C. Frankel.—The Daviess County Medical Society was addressed, Nov. 4, 1930 by Dr. William B. Negley and Allen L. Kincheloe, Owensboro, on 'Allergic Reactions in Man' and 'Treatment for Bronchial Asthma', respectively.—Dr. John W. Duke, Hindman, was elected president of the Kentucky Valley Public Health Association at a meeting of the society in Hazard, Dec. 19, 1930, among others, Dr. Fred W. Caudill, Hazard, spoke on 'Handling of Communicable Disease Carriers as a Public Health Duty'.—Dr. Wallace T. Patch, Evansville, Ind., addressed the Christian County Medical Society, Hopkinsville, January 20 on 'Differentiation of Angina Pectoris and Myocardial Infarction'.—Drs. Franklin Jelsma and Aura J. Miller, both of Louisville, spoke before the Harlan County Medical Society, Harlan, January 24 on 'Surgery of the Sympathetic System' and 'Pain and Its Relation to Clinical Medicine', respectively

MAINE

Bills Introduced—H 454 proposes to provide that all actions for malpractice against practitioners of the healing art be commenced within two years after the alleged malpractice. H 510 proposes to permit cities and towns to appropriate money to be expended in the city or town where appropriated, under the direction of the state department of health, for public health nursing. H 522 proposes to make incurable insanity of at least three years duration a ground for divorce. H 549 proposes to regulate the practice of cosmetology. H 970 proposes to accord licensure to physicians, nurses and certain hospitals by rendering services to persons injured in accidents, on any settlements or judgments obtained by the injured persons by reason of such injuries

MARYLAND

Bills Introduced—S 47 proposes to regulate the practice of cosmetology. H 94 proposes to require applicants for marriage licenses to file certificates from reputable physicians that the applicants are not afflicted with any contagious disease

Society News—Dr. Francis D. Coman, New York, who accompanied Comdr. Richard E. Byrd's expedition to the antarctic, gave an address, Dec. 16, 1930 at Johns Hopkins University School of Hygiene and Public Health, Baltimore, on 'The Climatology of the Antarctic in Its Relation to Health'. Gilbert F. Otto, Sc.D., and William W. Cort, Ph.D., spoke on 'Environmental Studies of Worm Infested Families in Tennessee'.—At a joint meeting of the Baltimore City Medical Society with the Gynecological and Obstetrical Society, January 9, speakers were Drs. William Schuman, on 'Fractured Pelvis in Obstetrics', William S. Gardner, 'Origin of Ovarian Epithelium', and Howard A. Kelly, use of radium in gynecology.—Dr. Major G. Seelig, St. Louis, addressed the

Oiler Historical Club, January 13, on 'Animal Behavior as a Factor in the Development of Medicine and Surgery'.—Speakers at the Baltimore City Medical Society's meeting, January 23, were Drs. Charles C. Habbston on artificial pneumothorax in the treatment of tuberculosis, Robert T. Miller, Jr., thoracoplasty, and Harvey B. Stone, 'What Should Be the Mortality of Appendicitis?'. The society was addressed, February 20, by Drs. Charles William Victor Richards on 'Dystrophia Adiposogenitalis', Francis F. Schwenker 'Protection of Infant Against Tuberculosis by Specific Inoculation' and Hugh W. Joseph, 'Treatment of Secondary Anemia by Iron and Copper'.—Dr. Lewis W. Hackett, International Health Division, Rockefeller Foundation, addressed the Society of Hygiene at Johns Hopkins University, Baltimore, January 7, on 'The Evolution of Malaria Control in Italy'.—There has been a 56 per cent decrease in the number of cases of communicable disease in Maryland in the last year; it is reported, 14,344 cases were noted in 1930 as compared with 32,639 in 1929.—The Baltimore County Medical Association was addressed, January 21, by Dr. Manuel G. Giehner on 'Acquired Serum Sensitivity', Arthur C. Niemeyer, 'Management of the Occiput Posterior Case', and Frank S. Lyan, 'Diagnosis of Appendicitis'.—Dr. Harvey B. Stone, Baltimore, addressed the Wisconsin County Medical Society, Salisbury, January 7, on 'Rectal Diseases from the Standpoint of the General Practitioner'.—Roentgenologists of Baltimore held a roentgenologic conference, February 6-7, having as their guests members of the New England Roentgen Ray Society, the New York Roentgen Society, the Philadelphia Roentgen Ray Society and the roentgenologists of Washington, D. C. Among the speakers were Dr. William S. Bier, whose subject was 'Treatment of Chronic Osteomyelitis by Maggots', Richard Dresser, 'Hodgkin's Disease of the Bones' and Julius Friedenwald, 'Clinical Significance of Roentgenological Findings in Chronic Appendicitis'.

MASSACHUSETTS

Bills Introduced—H 913 proposes to create a medical research board which shall distribute information obtained by it. H 592 proposes to require applicants for registration as nurses to be citizens of the United States

MICHIGAN

Bills Introduced—S 7 proposes a new act for the examination, regulation, licensing and registration of professional nurses and trained attendants. H 85 proposes to establish a state tuberculosis sanatorium in northern Michigan. H 65 proposes to provide for the registration and supervision of laboratories making chemical, serologic and/or bacteriologic laboratory tests to aid in the diagnosis and/or control of communicable diseases

MINNESOTA

Bill Introduced—H 522 proposes to provide for the sexual sterilization of certain socially inadequate inmates of state institutions

Society News—The annual conference of secretaries of the component societies of the Minnesota State Medical Association was held at St. Paul, February 7. Drs. Edward Starr Judd, President-Elect, American Medical Association, Rochester, and Ludwig L. Segge, Windom, president, Minnesota State Medical Association, were among the speakers.—Dr. Frank E. Burch, St. Paul, gave an illustrated address before the Minnesota Academy of Medicine, February 11 on 'Operative Treatment of Squint by Tucking Method'. Dr. George N. Ruhberg, St. Paul, presented a thesis on 'Paresis and Malaria'.

MISSOURI

Licenses Revoked—The license of Dr. Eric Anderson, Kansas City, was revoked by the State Board of Health of Missouri, Dec. 6, 1929. He was convicted of manslaughter by abortion, June 29, 1929, and was sentenced in the Jackson County circuit court to two years in the state penitentiary. He appealed to the Missouri Supreme Court, which affirmed the sentence of the circuit court, Dec. 19, 1930. The license to practice medicine in Missouri of Dr. Collis I. Roundy, St. Joseph, was revoked at a meeting of the State Board of Health of Missouri, January 26, for one year on the charges of unprofessional and dishonorable conduct.

Bills Introduced—S 224 proposes to provide for the vaccination of dogs against rabies. H 368 proposes to prohibit

the exclusion of children from school or the discharge of employees from service because they have not been vaccinated and are not otherwise immune to smallpox. H 426 proposes to establish a hospital for the inmates of Missouri prisons suffering with tuberculosis and other lingering diseases. H 403, to amend the workmen's compensation act proposes, among other things, (1) that an employer furnish an injured employee with necessary medical and hospital care for the first ninety days after the injury and in a sum not to exceed \$750 and (2) that every hospital or person rendering medical aid to the injured employee shall furnish on request full information to the commission, the employer or the employee.

New Research Institute and Hospital—The \$1,500,000 fourteen story building for the McMillan Hospital and Oscar Johnson Institute of Washington University, St. Louis, was opened in January. It was made possible by a bequest of about \$1,200,000 to the university from the late Mrs. William McMillan, St. Louis for an eye, ear, nose and throat hospital, and by a gift of \$650,000 from Mrs. Oscar Johnson her sons and two friends in memory of Mr. Johnson. Other gifts brought the McMillan fund to \$1,500,000, thus providing also for an endowment. On the first and ground floors are eye, ear, nose and throat clinics, administration offices, kitchen and service rooms. The second floor has six operating rooms, an auditorium seating 120 persons, a conference room and locker rooms for visiting physicians, nurses and medical social workers. The next five stories provide 150 beds, two floors being for private and semi-private patients of the full time and visiting staffs. One floor is for Negro patients, one for white ward patients and one for the care and study of infectious diseases of the eye, ear, nose and throat. The six upper floors will house the Oscar Johnson Institute for research and teaching ophthalmology and otolaryngology. Full time departments in these subjects are financed by a grant from the General Education Board of the Rockefeller Foundation. One floor is devoted to research in physics and physiology as applied to ophthalmology and otolaryngology. Three other floors planned for research in chemistry and bacteriology will be immediately put to use by a grant of \$50,000 a year for a period of five years by the Commonwealth Fund for a comprehensive investigation of trachoma. A roof garden furnishes recreational facilities for the staff and a sun parlor for the patients. The following appointments among others are listed: C. C. Bunch, Ph.D., as professor of applied physics, department of otolaryngology; William F. Werner, Ph.D., instructor in otolaryngology; George Holman Bishop, Ph.D., professor of applied physiology, department of ophthalmology; Dr. Percy Wells Cobb, associate professor of applied physics (ophthalmic staff); Dr. Harvey D. Lamb, assistant professor of ophthalmic pathology; Dr. Lee Wallace Dean, head of the department of otolaryngology; Louis A. Juhnke, Ph.D., associate professor of applied bacteriology and immunology, department of ophthalmology; R. Wendell Harrison, M.S., instructor in applied bacteriology and immunology; James A. Hawkins, Sc.D., associate professor of applied biochemistry in ophthalmology; and Alfred M. Lucas, assistant professor of cytology in otolaryngology. Rosalene A. Hetler, Ph.D., will have charge of the chemical studies of vitamin and food deficiencies and of the allergies in relation to eye diseases. Dr. Harvey I. Howard will direct research in ophthalmology and Dr. Lee Wallace Dean research in otolaryngology.

MONTANA

Bills Introduced—H 285 proposes to require the annual registration of practitioners of medicine or surgery and the payment of an annual fee of \$5 by each of them. S 68 proposes to make it the duty of all practitioners of the healing art who know or suspect that persons treated or examined are suffering from any communicable disease or any disease designated as notifiable in the regulations of the state board of health, to report such cases in writing to the county or local health officer having jurisdiction over the area in which such cases are located. H 102 proposes to accord liens to physicians, nurses or hospitals treating persons injured through the fault of another on any compromise, settlement or judgment obtained by the injured persons by reason of the injuries.

NEBRASKA

Bill Introduced—S 183 proposes that no person, other than licensed practitioners of medicine, surgery, osteopathy, chiropractic, dentistry, optometry or chiropody, or persons operating under their general supervision as assistants, shall in any manner whatsoever use, in connection with the human body, the roentgen ray machine in such a manner that roentgen rays shall penetrate any portion of a human body.

NEW JERSEY

Bills Introduced—S 155 proposes to authorize the medical examining board to examine in anatomy, physiology, hygiene, diagnosis of disease, histology, neurology, philosophy of naturopathy and practice of naturopathy persons who on March 31, 1921 were graduates of legally incorporated schools recognized by the board and teaching naturopathy, and who at that time were residents of New Jersey. If such persons receive a general average of 70 per cent or better the board must issue to them limited licenses to practice naturopathy. S 161 proposes to amend the law allowing charitable hospitals liens, by according such liens to all hospitals. A 192 makes insanity for fifteen years a ground for divorce. S 202 proposes to make it unlawful for any manufacturer, wholesale dealer or retail dealer, engaged in the sale or distribution for resale of drugs, medicines or poisons, to sell for resale such drugs, medicines or poisons to any retail merchant who is not permitted by law to sell them. S 221 requires the annual registration of pharmacists.

NEW MEXICO

Bills Introduced—S 72 and H 181 propose to require that applicants for licenses to practice any form of the healing art pass examinations in anatomy, physiology, chemistry, bacteriology and pathology to be given by a board of basic science examiners, before presenting themselves to their professional or cult boards for examination. H 123 proposes to create the office of inspector for the state boards of pharmacy, medical examiners and dental examiners to aid those boards in the enforcement of the medical, pharmacy and dental practice acts.

NEW YORK

Report on Lead Poisoning—The Bureau of Industrial Hygiene of the New York State Department of Labor has begun a series of investigations of industrial diseases in order to accumulate information for the conservation of the health of workers and the administration of compensation laws. Lead poisoning which ranks first in industrial diseases is the subject of the first report. Of 381 workers studied in twenty-five plants of fifteen industries 232 or 60.8 per cent gave definite evidence of lead absorption. The highest incidence, 100 per cent was found among lead burners who are exposed to fumes of lead oxide. Workers between 16 and 18 years of age were found most susceptible the incidence being 87.5 per cent. Duration of exposure appeared to be of little importance, 19 out of 28 workers who had been exposed for less than two months showed active lead absorption. The report presents in detail the results of the physical examinations and discusses symptoms, treatment and prophylaxis and relation to compensation. The bureau proposes that the term lead absorption be adopted to cover cases in which there is laboratory or other positive evidence that lead has been absorbed into the body whether or not there are clinical manifestations of disease. The term lead poisoning should be reserved for the investigators believe for cases in which toxic episodes such as lead colic, lead palsy and encephalopathy occur.

Bills Introduced—S 739 and A 1029 propose to make it a misdemeanor for any person to sell for purposes of resale

the United States Pharmacopeia or National Formulary preparation to any person, firm or corporation not registered with the board." S 740 proposes to require all packages containing barbituric acid to be so labeled. A 785, to amend the workmen's compensation act, proposes to designate as compensable occupational diseases any and all disabling diseases and disabling illnesses contracted in "any and all employments." S 594 proposes to provide for threefold damages for injuries caused by the unlawful furnishing, supplying or administering of dangerous drugs or medicines. A 980 and S 447 to amend the workmen's compensation act propose to make compensable any occupational disease or illness that is directly due or caused by any employment coming within the provisions of the act. A 911 to amend the workmen's compensation act provides compensation for disability or death which is not wholly due to or results from accidental injury arising out of and in the course of an employment. A 817 proposes that no hospital supported wholly or in part at public expense shall hereafter charge any fee or other compensation for medical services rendered while operating a clinic to which the public is invited, and that every such service rendered shall be without charge to the patient. A 786 to amend the workmen's compensation act proposes in effect to allow injured employees to select their own physicians. A 656 proposes to provide that all cosmetics be labeled to show that they are not injurious, the name of the compounder and the date of compounding and to require manufacturers of cosmetics to file their formulas with the state public health department. A 636 proposes to regulate the practice of chiropractic defined as diagnosis the palpating and adjusting by hand of the vertebral column and tissues. This shall not include the use of operative surgery or obstetrics or the administering or prescribing of drugs or medicine included in the pharmacopeia or materia medica.

New York City

One Thousand Five Hundred Welfare Societies—The 1931 issue of the Directory of Social Agencies, published by the Charity Organization Society in cooperation with the Welfare Council of New York City and twenty-four other organizations, lists approximately 1,500 organizations caring for the health, education, recreation, general welfare and relief needs of the city. Of this number, 518 are engaged in family welfare work, 557 in child welfare work, 651 in education, recreation or neighborhood activities and 655 in health work. There are in addition about 1,400 clinics, most of which provide free or nearly free health and medical services. More than 250 of the agencies listed are the headquarters of national or international welfare organizations.

Friday Afternoon Lectures—The spring series of Friday afternoon lectures given by the Medical Society of the County of Kings began, February 27, with Dr. Charles H. Smith, Manhattan, speaking on "Infant Feeding for the General Practitioner." Dr. Charles G. Heyd will present an illustrated address, March 6, on "The Liver and Gallbladder in Abdominal Infection," March 13 Dr. Elliott P. Joslin, "Role of the Practitioner in Preventing Diabetes and Diabetic Mortality," March 20, Dr. Joseph F. McCarthy, Manhattan, "Roentgenographic Delineation of the Urogenital Tract," March 27, Dr. Walter L. Niles, Manhattan, "Effects of Digitalis Therapy in Pneumonia," April 10, Dr. Paul A. O'Leary, Rochester, Minn., "Treatment of Syphilis," April 17 Dr. Binford Thronc, Brooklyn, "The More Common Skin Diseases," April 24 Dr. Foster Kennedy, Manhattan, "Relationship of the General Practitioner to Neurological Problems," May 1, Dr. Ralph I. Lloyd, Brooklyn, "The Protruding Eye as a Diagnostic Problem," and May 8 Dr. Joseph C. Regan, Brooklyn, "Use of Sera in Treatment of Acute Infectious Diseases."

NORTH DAKOTA

Bill Introduced—S 214 proposes to make it a misdemeanor for any person to experiment or operate on any living dog or cat for any purpose other than the healing or curing of the animal.

Licenses Revoked and Restored—At a meeting of the North Dakota State Board of Medical Examiners at Grand Forks January 8, the license of Dr. Charles I. Spannare, Fargo, to practice medicine and surgery in the state was revoked. Dr. Spannare pleaded guilty in the federal court to a charge of selling narcotics. The license of Dr. William R. Shortridge Flasher, who was pardoned by the state pardon board after serving five years of a ten year sentence in the state penitentiary at Bismarck for performing a criminal abortion, was restored.

OKLAHOMA

Bills Introduced—H 51 proposes to fix a rate which physicians may charge for professional calls. The rate is not stated and is apparently to be decided in the legislative committee in perfecting the bill. H 145 proposes to allow coroners a fee of \$5 for each inquest held and 10 cents per mile for travel while discharging their duties.

OREGON

Bills Introduced—S 250 proposes to create a department of osteopathy in the University of Oregon. S 252 proposes to make it the duty of all hospitals supported in whole or in part by public revenue or exempt from taxation to afford to all practitioners of the healing art the right to practice therein. S 255 proposes that certificates from licensed physicians stating that both parties to a proposed marriage are free from communicable diseases be required before licenses to marry are issued. The present law requires such a certificate only with respect to males. S 251, to amend the workmen's compensation act, proposes to allow injured employees the right to select their own physicians.

PENNSYLVANIA

Society News—Dr. Charles H. Marcy addressed the Pittsburgh Pediatric Society, February 13, on "Childhood Type of Tuberculosis," and Dr. Louis M. Kochin presented a case of epituberculosis—"Pulpluss Teeth as Foci of Infection" was the topic of discussion at a joint meeting of the Allegheny County Medical Society and the Odontological Society of Western Pennsylvania, February 17, in Pittsburgh the speakers were L. A. Wolf, Ph.D., L. E. Van Kirk, D.D.S., W. F. Swanson, D.D.S., Dr. Norman C. Ochsenhult and Dr. Joseph H. Barrich.

Philadelphia

Personal—Dr. Eugene Leroy Mercer has been appointed dean of the department of physical education of the University of Pennsylvania. Dr. William C. Ryan recently celebrated his twenty-third anniversary in the bureau of police, where he is assistant chief surgeon.

Society News—Dr. John R. Calk, St. Louis, delivered the annual B. A. Thomas Memorial Lecture before the Philadelphia Urological Society, February 23, on "Instrumental Treatment of Prostatism." Dr. Elliott P. Joslin, Boston, addressed the Philadelphia County Medical Society, February 25, on "Diabetes Mellitus: Diagnosis, Prognosis and Treatment." Dr. Frank C. Hammond, among others, addressed the Obstetrical Society of Philadelphia, February 5, on "Abdominal Operations During Pregnancy."

SOUTH DAKOTA

Bills Introduced—S 63 proposes to provide for a statewide census of the feeble-minded and for filing a list of the names obtained thereby with all marriage license issuing agencies. No marriage license may issue if one or both of the parties appear on the foregoing list. H 160, to amend the workmen's compensation act, provides that an injured employee be entitled to compensation for hernia must prove (1) that the hernia did not exist prior to the date of the accident and (2) that it was immediately preceded by an accident arising out of and in the course of the employment. If an employee refuses to submit to an operation he shall not be entitled to compensation.

TEXAS

Bills Introduced—S 182 proposes to accord hospitals treating persons injured by accident a lien on any settlements, compromises or judgments obtained by the injured persons by reason of such injuries. S 247 proposes to create an institution for crippled Negro children and to charge the state board of control with its location, construction, establishment and maintenance. H 272 proposes to regulate the practice of dental hygiene and to provide for the examination and licensing of such practitioner by the board of dental examiners. The licenses to be issued are to authorize such practitioners to remove calcareous deposits, accretions and stains from the exposed surface of teeth and just beneath the free margin of the gum, and to prescribe and apply any ordinary wash or washes of a soothing character, but not to perform any operation on the teeth or other tissues of the oral cavity. H 309 proposes to authorize the establishment of a new state hospital for the care of the insane, to be known as the West Texas State Hospital. H 400 proposes to authorize the construction

and maintenance of a hospital as a part of the prison system of the state, for the treatment and incarceration of all criminal insane. S 171 proposes a new law regulating the production, sale, dispensing and other traffic in narcotic drugs.

UTAH

Bills Introduced—S 48 proposes to accord liens to hospitals treating persons injured in accidents, on any judgments, settlements or compromises obtained by the injured persons by reason of such injuries. H 100 provides that accredited training schools for nurses shall allow no student to matriculate who has not had the equivalent of a high school education.

VERMONT

Bill Introduced—S 23 proposes to provide for the sexual sterilization of certain socially inadequate persons.

VIRGINIA

Health at Richmond—Telegraphic reports to the U. S. Department of Commerce from eighty-one cities with a total population of 36 million, for the week ended February 7 indicate that the highest mortality rate (24) appears for Richmond and the rate for the group of cities as a whole, 14.3. The mortality rate for Richmond for the corresponding period last year was 17.1, and for the group of cities, 13.7. The annual rate for eighty-one cities for the six weeks of 1931 was 14.2 as against a rate of 13.2 for the corresponding weeks of 1930. Caution should be used in the interpretation of these figures, as they fluctuate widely. The fact that some cities are hospital centers for large areas outside the city limits or that they have a large Negro population may tend to increase the death rate.

WASHINGTON

Bills Introduced—S 96, to amend the workmen's compensation act, proposes to define 'injury,' as used in the act to mean an injury resulting from some fortuitous event and to all other injuries, including occupational diseases growing out of and incidental to the employment. S 55 proposes to authorize certain school districts to maintain and operate dental clinics. H 239 proposes to permit dentists and dental students to obtain and possess human dead bodies for the purpose of anatomic inquiry or instruction. H 169 proposes that hereafter a person convicted of a capital offense shall not be entitled to any inquisition or trial to determine his sanity. On satisfactory evidence being presented to the governor however that any person convicted of a capital offense has become insane subsequent to the conviction the governor may cause such person to be examined by such experts as he, the governor, may choose.

WEST VIRGINIA

Bills Introduced—H 165, to amend the workmen's compensation act, proposes to make employers liable for such sums for medical, surgical dental and hospital treatment accorded an injured employee as may be reasonably required not however, to exceed \$800. S 105 proposes to prohibit the sale and distribution of veronal, barbital, or any preparation or compound containing diethylmalonyl urea or diethylbarbituric acid, except on the written prescription of a physician. H 218 proposes to authorize the public health council to issue certificates to practice medicine and surgery to all persons who apply before Jan. 1, 1932, who have had two years study in a recognized medical school and who at the time of said study have had twenty years experience practicing medicine and surgery in the state.

WISCONSIN

Bill Introduced—S 71 makes it unlawful to sell any food drink, medicine or toilet preparation intended for human use, or any antifreeze agent for motor vehicle radiators which contains wood alcohol, methanol or methyl alcohol. Sales may be made only in containers labeled 'poison.'

WYOMING

Bills Introduced—S 5 proposes among other things to amend the medical practice act by stating the procedure to be followed by a licensee in appealing to the court from a decision of the board of medical examiners revoking his license to practice. S 49 proposes a new pharmacy practice act. H 187 proposes to make it unlawful for the board of trustees or the governing board of any hospital supported in whole or in part by public revenue to refuse to allow any licensed practitioner of the healing art to practice in said hospital.

GENERAL

Society News—The seventeenth annual observance of National Negro Health Week will be conducted, April 5-12. The objective for this year's observance is the establishment of National Negro Health Week on a year-round basis. It is requested that the results of the health week be sent to the National Negro Health Week Committee, Howard University, Washington, D. C.

International Hospital Congress—The second International Hospital Congress will be held in Vienna in the early part of June. A pre-convention tour of study and inspection of hospitals in London, Copenhagen, Berlin, Prague and Budapest is planned for the American contingent. It is expected that an international hospital association will be formed during the congress. Details may be obtained from E. H. L. Corwin, Ph.D., secretary general, 2 East One Hundred and Third Street, New York.

Translation of Incomplete Credentials—Frequent requests for translation of American certificates covering only high school and one year college work have been reported to state boards of medical examiners recently. It is said that students who submitted these incomplete credentials have been directly admitted to foreign medical schools, probably because of a misapprehension on the part of foreign university authorities of the nature of American schools. The practice is believed to be a definite attempt to shorten the required American college course.

Report of Ella Sachs Plotz Foundation—According to the seventh annual report of the Ella Sachs Plotz Foundation for the Advancement of Scientific Investigation seventy-eight applications for grants were received during the last year, sixty-two of which came from twelve different countries in Europe and Asia and sixteen from the United States. Twenty-five grants were made, one of these being a continued annual grant. Twenty-one new grants were made to scientists in countries outside the United States. In the seven years of its existence, the foundation has made 120 grants to investigators in various countries. In accordance with the policy of giving preference to researches on a single problem, four investigations aided in 1930 bore on the general subject of nephritis. In 1929 there were seven, in 1928 three and in each of the four preceding years four grants for work in this field. Applications for grants for the year 1931 should be in the hands of the executive committee before May 1 and should include statements as to the character of the proposed research, the amount of money requested and the objects for which the money is to be expended. Applications should be sent to Dr. Joseph C. Aub, Collis P. Huntington Memorial Hospital, 695 Huntington Avenue, Boston.

Medical Aid in Drought Area—Plans for medical relief in the states that have been most severely affected by the drought were formulated at a conference of health officers called by Dr. Hugh S. Cumming, surgeon general of the U. S. Public Health Service, at Memphis, Tenn., February 10. The problem is to be approached from five different angles according to the local situation. Under the federal appropriation of \$2,000,000 existing county or local health units are to be aided by the assumption of obligations when local funds are lacking on account of inability to collect taxes, bank failures or other justifiable causes and by the employment of additional personnel to meet emergency needs as a temporary measure only. County health units will be established in counties which have no organization on the following conditions: that at least one-third of the expense be borne by the local authorities; that one-third be borne by the state; or that at least one-half of the expense be borne by the state and local authorities together. Mobile health units to provide temporary health services will be furnished as part of the state health administration to be supported by state funds to the greatest extent possible. Individual county nurses and sanitary inspectors are to be provided for counties in which they are needed and in which organized health departments cannot at present be maintained. Finally, state boards of health are to be supplemented by supervisory personnel if needed for emergency work.

Medical Bills in Congress—H. R. 17039, introduced by Representative Leavitt, Montana, proposes to construct and equip a hospital on the Blackfeet Indian Reservation, Montana. The House Committee on Rules has voted a special rule for the consideration of S. 255, the Jones maternity, infancy and rural hygiene bill which will bring the bill before the House for consideration probably during the week ending, February 26 (H. Res. 369). S. 5465 has been reported to the House without

amendment, enabling institutions incorporated under the laws of the District of Columbia and conferring any and every kind of degree, whose activities are carried on exclusively in a foreign country, to use in their titles the words "American," "Federal," "United States," etc (H Rept 2751) S 5959 has passed the Senate authorizing the Secretary of the Treasury to purchase the laboratory of the state of Montana, constructed for the prevention, eradication and cure of spotted fever. A similar bill in the House, H R 16915, has been favorably reported to the House with amendments (H Rept 2798) S 5984 has been favorably reported to the House, without amendment, providing for the erection, for the District of Columbia of a sanatorium for adult tuberculous persons (H Rept 2759) S 6171 has passed the Senate, regulating the prescribing and use of waters on the Hot Springs Reservation, at Hot Springs, Ark. A similar bill in the House, H R 14275, has been reported to the House, with amendment (H Rept 2677) S 1812 has been reported to the House, without amendment, authorizing the annual collection of statistics relating to crime and to the defective dependent and delinquent classes (H Rept 2757) H J Res 480 has been reported to the House, without amendment, authorizing an appropriation to defray the expenses of participation by the United States in the conference on the limitation of the manufacture of narcotic drugs to be held at Geneva, May 27, 1931 (H Rept 2688) H R 4811 has been reported to the House without amendment, authorizing the Bureau of Mines to manufacture 1 gram of radium (H Rept 2802) H R 16658 has passed the House authorizing an appropriation of \$2,850,000 for additional hospital and domiciliary facilities at the branches of the Bureau of National Homes. H R 16982 has passed the House, authorizing an appropriation of \$12,500,000 for additional hospital, domiciliary and outpatient facilities for veterans. This bill has been favorably reported to the Senate, with amendments which, among other things, propose to increase the appropriation authorized by the bill to \$20,877,000 (S Rept 1665) S 6147 introduced by Senator Hatfield West Virginia proposes to authorize the construction of a veterans hospital in northern West Virginia. S 6178 introduced by Senator Bingham, Connecticut, and H R 17140, introduced by Representative Goss, Connecticut, propose to regulate the use and sale of wood alcohol. H J Res 505, introduced by Representative Celler, New York, proposes to remove the frequency and quantity limitations imposed on physicians with respect to the prescribing of vinous and spirituous liquors. H R 17094, introduced by Representative Leavitt, Montana, proposes to construct and equip a hospital on the Rocky Boy Indian Reservation in the state of Montana.

Deaths in Other Countries

Emil Fronz, author of books on children's diseases, Dec 31, 1930, aged 70.—Archibald Leitch, director of the research institute of the London Cancer Hospital and professor of experimental pathology, University of London, January 28, aged 52.

Government Services

Resignations from the Navy

The following resignations from the navy have recently been announced: Lieut Jasper S. Hunt, effective January 3, Lieut Paul H. Milton, effective Dec 28, 1930, Lieut William C. McBride, effective Nov 28, 1930, Lieut Comdr William A. Stoops, effective February 1, Lieut Connie H. King, effective Dec 13, 1930, Lieut Roland G. Vaughan, effective January 6, Lieut Harold Simons, effective March 22.

Change of Station in the Navy

Lieut Comdr Rex H. White to duty involving flying, commander carrier division 1 U S Fleet. Lieut Bartholomew W. Hogan to the naval hospital Washington, D C. Lieut Julian Love from the Receiving Ship to the naval hospital New York. Capt Holton C. Curl detached as assistant chief of bureau of medicine and supplies and ordered to duty as district medical officer, fourth naval district Philadelphia, Lieut Comdr William D. Davis to marine barracks, Quantico, Va. Lieut Wilbur F. Kellum from the U S S *Maryland* to the U S Naval Medical School Washington D C. Lieut Farra L. Read from the Asiatic Squadron to the United States, Lieut John D. Foley from the naval hospital, New York, to

the U S Receiving Ship, San Francisco, Capt John B. Deane to the bureau of medicine and surgery as assistant to the chief of the bureau, Capt Richmond C. Holcomb to command the naval hospital, League Island, Philadelphia, Lieut Edward E. Evans from the U S S *Pittsburgh* to the fourth regiment U S Marines, China, Lieut Comdr Walter A. Fort from the naval hospital, New York, to the Asiatic Station, Lieut Wilfred P. Dana from the naval air station Hampton Roads, Va. to the first brigade, U S Marines, Haiti, Capt Edgar L. Woods from the Receiving Ship, New York, to the Bureau of Medicine and Surgery. Lieut Harold I. Brown from the naval training station, San Diego, Calif., to the U S S *Henderson*.

Examination for Entrance Into Public Health Service

Examination of candidates for commission as assistant surgeon in the regular corps of the U S Public Health Service will be held at Washington, D C, March 9. Candidates must be 23 years and not over 32 years of age. They must have been graduated in medicine at a reputable medical college and have had one year's hospital experience or two years professional practice. They must satisfactorily pass oral, written and clinical tests before a board of medical officers, and undergo a thorough physical examination. Surgical candidates will be recommended for appointment by the President, with the advice and consent of the Senate. Request for information or permission to take this examination should be addressed to the surgeon general, U S Public Health Service, Washington, D C.

Report of Food and Drug Administration

The report of the Food and Drug Administration U S Department of Agriculture for the year ended June 30, 1930, shows that 1,105 seizures and prosecutions of domestic products were made and that 3,433 import samples were detained. In the course of the operations 36,068 samples of food and drugs were collected and examined. Of these 3,347 were examined for arsenic, a precaution necessary because of its use as a spray for fruit trees. Sixteen outbreaks of alleged food poisoning were investigated and pathogenic bacteria were identified in five. Work conducted by the administration in the control of traffic in fresh, dried and canned fruit infested with worms centered to a large extent on figs, 625 lots (20,725,310 pounds) of which were examined, of this quantity 2,853,840 pounds were reexported and 870,000 pounds destroyed. Improvement has been made in the quality of canned salmon, only three prosecutions having been made. In the tuna fish industry, however, investigators found conditions similar to those that had existed in the salmon industry. In cooperation with the California state board of health a vigorous campaign was carried on in which twenty-four seizures were made, and the system of state inspection was extended to insure better local control. More than 5,000 cases of canned tomatoes adulterated with water were seized. Thirty-five carloads of frost damaged grapefruit and oranges were condemned before they were shipped from the citrus belt of Texas. Under the federal tea act, 207,884 pounds of tea were rejected, of 84,732,677 pounds offered for importation during the year. During the year 5,748 samples of milk were examined under the federal import milk act, which applies principally to milk from Canada. An excessive bacterial count was found in 369 samples. 584 plants and 4,127 dairy farms were inspected. 108 permits were suspended. Two hundred and forty-nine seizures of falsely and fraudulently labeled proprietary medicines were effected, it was claimed that 135 of these were remedies for influenza. Ninety-seven court actions involving adulterated or misbranded pharmaceutical preparations were brought during the year. Thirty-nine consignments of ether that failed to meet pharmacopeial standards were removed from the market. The administration cooperated with the Bureau of Prohibition and state health officials in the seizure of twenty-two lots of a product sold as Jamaica ginger. In the field of research the administration reports the development of a biologic test for ergot, methods for determining the presence of tartaric and citric acids and work on similar problems. Assistance was given to the Post Office Department in the handling of 130 cases in the effort to eliminate from the mails such contraband materials as fake medicines, cure-alls and poisons. Thirty-six cases were disposed of as follows: fraud orders issued in 12, penitentiary sentences imposed in 2, grand jury indictments issued in 3, prosecutions abandoned because of insufficient evidence in 2, seventeen concerns discontinued business. The name of the organization was changed, July 1, 1930 to the Food and Drug Administration.

The Sun Treatment of Tuberculosis in England

When the sun treatment of surgical tuberculosis was established, mainly by work of Auguste Rollier at Leysin, Switzerland, the idea prevailed that the more sunny climates of the continent and the high altitudes of the Swiss mountains were if not necessary, a great advantage. But the sun treatment of tuberculosis has been so developed in England by Sir Henry Gauvain at the Treloar Cripples Hospital and College Alton (Hampshire) and at its marine branch (Sandy Point Hayling Island) that equally good results are now claimed. Indeed, in his recent residential address to the congress of the Royal Institute of Public Health, Sir Henry Gauvain declared that, in spite of its high proportion of cloudy and misty days, the English climate had the advantage. If sun treatment is of such value in the prevention and treatment of disease, why not send the patient, people asked to the most sunny climate possible? To this Sir Henry replied by another question. Is mortality appreciably lower in countries regarded as ideal for insolation? Is tuberculosis appreciably less? The reply is in the negative. On equatorial islands where sunlight is always obtainable and the islander can live nude all the year round, tuberculosis will rapidly infect and kill the unimmunized native. The results of the sun treatment are in some cases brilliant, in others disappointing. This Sir Henry explains by his 'theory of varying stimuli and varying response. No completely satisfactory explanation has been given of the value of the general light bath. Sonne's statement that it largely depends on thermal effect is not adequate, nor does the raising of hemobactericidal power furnish the clue. Sir Henry Gauvain suggests that the good effects depend on the stimulus of seasonal and even hourly variation in the conditions of exposure—the position of the sun in the heavens, the density and purity of the atmosphere, the amount of sky shine and the intervention of passing clouds. The morning light though less intense than that of midday has the greatest value because of the light shock following the darkness that has preceded. Continuous exposure to sunlight in summer is not so beneficial as alternations of light and shade and of heat and cold. Sun treatment is greatly aided by the associated aerotherapy—the stimulus to the production of heat by the body produced by the impact of cold air. Therefore the English climate by its very changeableness lends itself to open air treatment. Sun treatment is shock treatment comparable to protein shock.

The report, just issued of the Treloar Cripples Hospital shows remarkable successes. Children up to the age of 12 suffering from tuberculous disease of bones or joints and a limited number of general orthopedic cases are admitted. Crippled lads from 14 to 18 are trained in handicrafts. Of 176 patients who had completed their treatment in the year 170 were sent out with the disease arrested. These included 34 cases of spinal disease, 47 of hip disease, 21 knee and 68 of 69 other tuberculous lesions arrested. The marine branch offers the stimulus of climatic change and new environment to patients who need the tonic of seaside conditions. It is found that very crèche and young patients are not benefited to the extent that stronger and older patients are. The stimulus is beyond their power of response. Graduated sea bathing and heliotherapy are given to the bulk of the patients in addition to the ordinary orthopedic and general treatment. Conservatism in the treatment of surgical tuberculosis has been followed ever since the establishment of the hospital twenty-one years ago and is now more firmly established than ever. But the help of surgery is occasionally sought for bone grafting to immobilize

joints more completely, though in children with only a modified success. Sir Harold Gillies and Mr Kilner have done some highly successful and extensive plastic operations for facial restoration following lupus after the disease has been cured by the light department.

A New Study of Diet

Almost all the data as to normal diets are those of foreign investigators. The medical research council decided that a more accurate quantitative knowledge of the normal diets of the inhabitants of this country was desirable for guidance both in health and in disease. It therefore commissioned Dr E P Cathcart, professor of physiology in the University of Glasgow, and Dr A M T Murray to undertake a study of nutrition. This study took the form of an inquiry into the diet of 154 families of St Andrews, Scotland, based on the help given and the records kept by the staff of the James Mackenzie Institute for Clinical Research. It may be remembered that this institution was founded by the late Sir James Mackenzie to undertake clinical research into the early stages of disease, a subject which he held to be important and neglected. The families studied belonged to all classes of the population. One of the main conclusions reached was that for the persons examined the consumption of protein was much below, that of carbohydrate below, but that of fat much above the standards laid down by the accepted authorities. The consumption also deviated in the same directions from the standards recommended by the Royal Society during the war, which were adopted as the basis of the measures taken by the government during the late emergencies of that struggle. The accompanying table shows the results of the present study as compared with the standard diets of Voit and Rubner.

Percentage of Total Calories

	Protein	Fat	Carbohydrate
Voit (moderate work)	16	17	67
Rubner (moderate work)	17	16	67
Present study	11	35	54

Thus the percentage of calories supplied by fat in the population studied was more than twice as great as in the standard diets and even among the poor the percentage was found to be much higher than had been supposed. There is no doubt that the St Andrews diets are in keeping as regards their proportions with the type of dietary common in this country and that they approximate closely to the average for the United States. Another striking point is the relative lowness in protein. The quality as well as the quantity of food consumed was found to be largely a question of income. With rising income the tendency was to purchase foods rich in protein such as butcher meat with sometimes a decrease in the amount of starch consumed. Nevertheless there is a tendency when the income increases to spend more on fat. The miners with their higher wages consume more fat than the agricultural laborers. During the war the shortage of fat was the great trouble in dietary. In certain parts of Europe it was followed by a sharp increase in the incidence of tuberculosis, and when the supply of fats became normal again the incidence of tuberculosis immediately declined.

As regards the total energy value there was no evidence of lavish consumption on the part of those better off though naturally their intake was higher than that of others. A problem which puzzled the investigators was that while 3100 calories a day satisfied the manual laborer the sedentary group consumed more than 3300. Where did the extra calories go? It was agreed that the sedentary class expended much energy in walking and playing games but it was doubtful whether they expended anything like the amount of energy represented by the extra food. It followed therefore that the extra food

must be stored or metabolized in some other fashion. As obesity was not a marked feature of this section of the population it must follow that the explanation was *luxus consumption or secondary dynamic action*.

Action Against Drug Traffickers

The League of Nations Advisory Committee on Traffic in Opium has adopted the following resolutions, submitted by the representatives of Great Britain, Belgium, Italy and Spain. No firm which has knowingly manufactured or supplied for illicit traffic drugs falling under the Geneva convention should be allowed to hold a license to manufacture or trade in these drugs. The committee also recommends that the same rule be applied to narcotics derivative of morphine or cocaine even though they do not at present fall under the Geneva convention. As there is evidence that illicit traffickers can move freely from country to country in carrying out their operations, the committee recommends that passports and visas be refused to persons so engaged or be canceled if already issued.

Chemotherapy in Tuberculosis

There is general agreement among tuberculosis specialists that the results of chemotherapy, if not definitive, are at least important in well chosen cases. In support of this treatment, Prof. Leon Bernard presented a paper that favors continuing the trials. The Société des médecins des hôpitaux de Paris, in a recent discussion enlarged the field and included communications on the use of other chemical substances that may reinforce or replace the use of gold salts. Messieurs Flandin, Lecocq, Maisson and Thurolon gave their opinions based on numerous therapeutic trials made not only with gold salts but also with salts of cerium and molybdenum. After pointing out how difficult it is to interpret the improvement observed in pulmonary tuberculosis, which may appear spontaneously, they said that the best criteria of the therapeutic effect are the temperature, the weight, bacilli in the sputum, and, the radiologic modifications. In using gold salts the authors prefer a fat soluble compound in the form of intramuscular injections, as it appears to expose the patient less to reactions sometimes observed after intravenous injections. The results in most cases have been satisfactory. As regards cerium, whether it is given by mouth or injected intramuscularly the authors consider that the results secured were at least equivalent, which makes it possible to alternate with the gold treatment. Molybdenum, on the basis of more recent trials, produced, it seems better results than other products hitherto employed. It dispels the bacillus from the sputum, while, at the same time, the general condition improves rapidly.

Parathyroid Extract in Arthritis Deformans

At a recent meeting of the physicians of the hôpitaux de Paris, chronic rheumatism was discussed. For several years Leopold Lévy and Henri de Rothschild have called attention to the role of the thyroid secretion in arthritis deformans, and they have introduced a form of treatment with powdered thyroid substance which has often given good results. At present, extracts of parathyroid glands are being tried, although the parathyroid glands are supposed to have an action rather antagonistic to that of the thyroid. Weissenbach, Fraunton, Perles and Seidmann have announced the results that they have secured over a period of more than a year in a dozen cases of chronic arthritis deformans in which they used parathyroid therapy subcutaneously in successive and repeated series with a dosage of from 1 to 2 cc daily. In general an immediate local and painful reaction follows the injection, which produces marked relief, a quieting of the pain symptoms and

a frank functional amelioration, which persists for several hours. The improvement appears to be more stable if a sufficient number of injections have been given. When the treatment is stopped, one often observes recurrences of the articular symptoms. In general, the final results are satisfactory. The joints become supple and the general condition improves. However, one must watch for signs of intolerance. The authors are unable to reach a definite conclusion with regard to the nature of the action of this glandular extract.

The Nature of Beriberi and of Scurvy

At a meeting of the Société de médecine et d'hygiène tropicales, discussion arose as to whether or not beriberi and scurvy are, as it commonly supposed, deficiency diseases. In the opinion of R. Dumas, beriberi is not a deficiency disease but rather a toxic infection. He reports in support of this theory several cases that he observed in the colonies. In these cases the beriberi was not due to a deficiency, for there was an abundance and variety of foods, but was plainly due to a disease of the rice grain. White rice spoils rapidly, whereas the brown rice, protected by its epicarp, is less frequently contaminated by cryptogams. As for scurvy, there is nothing to prove that it is a deficiency disease. The author, who had occasion to observe numerous cases of scurvy during a long voyage, gave several theories on the subject. Marcel Leger shares the view of Dumas on the pathogenesis of beriberi. He had observed Tonkin cases that left no doubt as to the toxic infectious nature of the disease. He had seen contagious cases in Hanoi. Mr. Libermann stated that in the Indies beriberi occurs in the regions in which the rice is milled by mechanical process. In Indo-China he never saw a case of contagion in the hospital. It is evident therefore, that the question is complex and difficult to decide. Mr. Nattan Larrier, who thinks that beriberi is contagious, referred to the cases of contagion cited by Mr. Jernselme. On the plantations of Cochinchina, where only a day's supply of rice is milled at one time no cases of beriberi are ever observed. This discussion which opens up again scientific questions hitherto regarded as settled, is somewhat perplexing for it leaves unexplained the cases in which beriberi has been reproduced experimentally in animals by a suitable defective diet and has been cured by a return to the normal diet, the same as in rickets.

BUDAPEST

(From Our Regular Correspondent)

Jan. 9, 1931

International Stomatologic Congress

The Association Stomatologique Internationale will hold its first international congress at Budapest, September 27. The last congress, which was held in Venice was a national Italian congress, but representatives of thirteen nations were present. In place of the resigning chairman, Dr. Chompret, Paris they elected professor Szabo, Budapest, and instead of Dr. Herpin, Paris, general secretary, they elected Dr. Sturm, Budapest. The congress will take place with the support of the Hungarian government and the city of Budapest. Lectures will be held by invited experts from all parts of the world. There will be also an exhibition of dental and surgical instruments. The office of the congress is in Budapest, IV, Varoshaz uccsa 14. The chief secretary is Dr. Morelli, lecturer to the University of Budapest.

Intravenous Resorcinol Treatment in Acute Polyarthritis

At the Budapest St. Stephan Hospital experiments were made with the intravenous use of resorcinol in cases of acute polyarthritis. They were encouraged by the results achieved with similar administration of resorcinol in septic cases. As reported by Dr. Stephan Roth, junior physician during the period 1927-1930 out of 258 patients suffering from polyarthritis they

selected 105 patients as suitable for intravenous treatment. The patients were rather young, and their disease was acute, with high fever, violent arthritic pains, tumescence and redness, that is, the attack was primary and not a relapse. In subacute and in chronic cases the intravenous resorcinol treatment is not indicated. The method is not contraindicated in acute cases complicated with endocarditis. Thus, of their 105 cases, 65 presented endocarditis. Resorcinol was given in every case intravenously in a dose of not less than 1 Gm dissolved in freshly distilled and sterilized water. The injection is accompanied by buzzing of the ears, fainting and accelerated breathing, which last for two or three minutes. Every patient gets, in all, from 5 to 6 Gm of resorcinol, without any harm whatever. The good effect of resorcinol may be augmented by the simultaneous oral administration of sodium salicylate. Of 105 patients, 56 have been cured, 20 improved and 29 less improved, so that in the cases of the latter category other methods of treatment had to be resorted to. In the most favorable cases the injection is followed by profuse perspiration, and the fever falls by crisis. This is succeeded by a better general feeling and a decrease of pain, and the tumescence and redness of the swollen joint abates from hour to hour. Some of the cases have been under observation more than eighteen months and as yet no relapses have occurred.

Restitution of the Family Physician

In late years, when critical economic conditions prevailed in Hungary, private practitioners complained of the ever increasing number of sickness insurance companies, which admit as members also people who can afford to pay for medical services. As a result the old family physician system, which was a boon to both families and physicians, almost entirely ceased. Physicians in trying to resuscitate this system have appealed to the medical association for the elaboration of new rules that would satisfy physicians and at the same time also the public. The board of directors of the association intends to regulate the family physician system as follows: the position of a family physician commences with the first of January and ends with December 31. If the connection is interrupted after the first of April, the whole year's salary has to be paid by the patient. The minimal price in Budapest is 100 pengó (about \$18) while outside Budapest it is 50 pengó (about \$9). In the larger towns the branches of the association have to fix the prices of the family physician, paying due attention to the minimum. If the patient moves farther than 2 kilometers from his previous dwelling (in relation to the physician's house) a new agreement should be made. Consultations with other physicians, operations, and night calls have to be paid for extra.

A Disease of Paprika Cutters

Paprika is a special Hungarian condiment, which when dried becomes red and in this state it is cut and milled, whereby it becomes a condiment. Dr F Kovacs in a paper read before the Budapest Royal Medical Society described a disease affecting paprika cutters. He often observed a peculiar disorder of the lungs the symptoms of which resembled those of tuberculosis, while a roentgenogram reveals a picture reminding one of a diffuse broncho-alveolitis. Paprika cutting consists of cutting out the ribs of the vegetable because this contains mostly capsicum and thus paprika loses its excessive smartness. It seemed probable that the disease was caused by the rising paprika powder but this is contradicted by the fact that the paprika millers did not show any such manifestations although they are grinding the strongest paprika powder. The causative agent is a mold which the cutting women constantly inhale. The disorder of the bronchi is caused by the fine spores. The disorder may involve the pleura and may cause also severe bronchiectasis. It should not be confused with tuberculosis. It is easily differentiated by microscopic examination of the sputum. The most important question is one of prophylaxis. This is not difficult because the cough occurs only if moldy paprika is

being worked up, from this, it is obvious that paprika should be worked up in a fresh state. In practice this is well nigh impossible, because this is a small industry, and most of the establishments employ fifteen or twenty women who want to keep working for the whole winter. Thus they have to store the autumn picked paprika, which gets moldy when standing in the storehouse. Dr Kovacs urged that a law be made requiring the frequent turning of the paprika in the storehouse to prevent its getting moldy.

ITALY

(From Our Regular Correspondent)

Dec 31, 1930

Meeting of Anatomical Society

The Società italiana di anatomia held its second national session in Florence, under the chairmanship of Prof Giulio Chiarugi, director of the institute of anatomy of the University of Florence.

Professor Teroni of Padua spoke on the first topic on the program, "The Newer Morphology of the Autonomic Nervous System." The speaker explained the methods that have been developed by morphologic research on the vegetative system, mentioned the physiomorphologic discoveries of Gaskell-Langley and discussed certain subjects pertaining to the development and to the structure of the sympathetic system. He referred to the opinions on the origins of the sympathetic system and concluded that, while an active migration of sympathetoblasts from the neural tube and from the neural crest is not certain, there is evidence of a directive, organizing action of the neuraxon on the development of the autonomic system. The speaker considered then the question as to whether the cells of the autonomic system have a particular appearance that distinguishes them from other central and peripheral nerve cells and discussed the character of the myelination (or the absence of myelination) of the nerve fibers as a differential criterion. Finally Teroni discussed the phylogenetic significance of the autonomic system, including the sympathetic and the parasympathetic, and pointed out the difficulty of identifying in the invertebrates a system analogous to the autonomic system of the vertebrates. He recognized, however, for all groups of the latter the existence of a preganglionic and postganglionic sympathetic and parasympathetic system and considered the autonomic system as genetically, as well as functionally, connected with preganglionic centers.

EXPERIMENTAL RESEARCH ON THE CEREBELLUM

Professor Simonelli of the University of Florence presented a paper on "Morphologic Data as a Guide in Experimental Researches on the Cerebellum." The speaker recalled the newer morphologic division of the cerebellum according to Bolk and others and raised the question as to within what limits one can recognize a distinct and separate function in the various cerebellar formations. The cerebellovestibular relations constitute a point of generic interest. Until recently there was a tendency to hold that in the cerebellum are located the centers of the labyrinthine reflexes but today on the basis of recent research of the Magnus school and the Florence school of physiology it must be accepted that while the action of the cerebellum takes place through the operation of these reflexes their centers are however doubtless located outside the cerebellum itself. As regards the functions of the various lobes of the cerebellum numerous experiments of demolition and of cortical stimulation have established rather constant facts with reference to the anterior lobe, certain zones of the posterior median lobe, the crus primum and the crus secundum. Also with reference to the other areas accurate researches are not lacking but the physiologic data that have been secured do not appear sufficiently controlled by histologic examination and do not present sufficient agreement between the phenomena of suppression and those of stimulation.

In addition to the official papers and the general discussion there were other communications. As a general conclusion, it was emphasized that the greater part of the research carried out thus far in this field is based on too few cases, considering the great importance of statistical studies on this problem. There was a possibility thrown out of carrying on systematic research simultaneously in the various provinces of Italy.

Professor Spadolini, physiologist of the University of Siena presented a communication illustrated by the projection of numerous photomicrographs on the genesis of blood platelets.

Professor Pensa of Pavia spoke on the structure of the cerebellum, taking up the discussion of certain problems of neurologic interest.

Palermo was selected as the meeting place for the next convention, and Professor Luna, director of the Institute of Anatomy of the University of Palermo was chosen president.

Congress of the International Society of Microbiology

The Italian section of the Società internazionale di microbiologia will hold its third congress in April, in Milan. The following topics will be discussed: (1) Pathogenesis of Diseases of Plants, presented by Professor Montemartini of the University of Palermo; (2) The Newer Knowledge Concerning the Biology of the Tubercle Bacillus discussed by Professor Puntieri of the University of Rome, and (3) Hypersusceptibility in Disease, with paper by Professor Zironi of the University of Milan. In addition, Professor Pepeu of the Istituto sieroterapico in Milan will present a communication entitled "Modern Views on Antidiphtheritic Vaccination."

The Medicopedagogic Convention

The second National Medicopedagogic Convention was held in Milan under the auspices of the Associazione pro infanzia anormale and the Lega (league) per l'igiene e la profilassi mentale. The purpose of the meeting was to stimulate an exchange of ideas between competent persons interested in scientific and practical problems concerning the treatment and education of children who have mental defects or defects of speech or hearing. On this occasion, a demonstration was given of the organization as completed by the municipality of Milan, in the special institutions for persons with mental defects, which have all the necessary aids for complete and rational medicopedagogic assistance. Professor Meder, in his inaugural address, described the work accomplished during the past decade, by the Child Welfare Society, which culminated in the creation of the special Zaccaria Treves school.

Professor De Sanctis, director of the Clinica neuropsichiatrica of the University of Rome, discussed the measure of success that has been secured in the rendering of medicopedagogic aid in the various forms of mental instability in children. He explained the medical and the pedagogic sides of the problem. As to the medical side, De Sanctis emphasized the great frequency with which the psychic anomalies of children are the effect of organic diseases of the brain of an inflammatory nature and particularly, of an infectious type, among which congenital syphilis plays an important part. As for the pedagogic side, the speaker considers that the environment, both physical and moral, has a great deal to do with the development of mental disease and should therefore be surveyed and, if necessary, changes made while there is time. The organic constitution before the mental disease developed should be studied as a concomitant cause, and such information is most often furnished by the environment.

A Veratti referred to the activity developed by the juvenile court of Milan during its first two years. It was only natural that a controversy developed between two opposing scientific schools: one of which approves and the other rejects the collaboration of the psychiatric expert with the magistrate. The Milan tribunal taking advantage of the discretionary powers conferred on it by law considered the opinion of the medical specialist necessary in every case.

Dr. Albertini and Professor Corberi offered a paper on the present status and the indications of medicopedagogic aid in children affected with mental anomalies. The speakers explained the provisions made for abnormal and for backward children; the law pertaining to maternity and childhood, and consisted of ambulatoriums for diagnostic observations, under the direct of medical specialists, schools in psychopathic hospital and independent schools the purpose of which is the adaptation, as far as possible, of mentally abnormal children to life, and carry out the specific prophylaxis to reduce the delinquency minors. There are in addition differential classes for backward children in the elementary public schools.

Instruction in Occupational Medicine

By a recent circular letter sent to the faculties of medicine in the universities the minister of public instruction established an official course in medicine pertaining to occupational diseases. The purpose of the instruction will be the training of experts who can then be assigned to the welfare institutes for hygienic and social protection of workmen. The faculties of medicine in addition to adding the new branch of study to its program, must advise the students to take the course.

Appointment of Director of Health Department

Dr. Gaetano Basile has been appointed director general of the department of public health. Dr. Basile was a pupil and assistant of Professor Pagliani and later, provincial physician. His services as hygienist were of great importance during an epidemic of plague that occurred in Naples in 1901, and during the cholera epidemic of 1911 in Messina. Prof. Arcangelo Ilvento was appointed assistant director general of the hygienic and sanitary services of Italy. He is at present director of the sanitary services of the Italian Red Cross Society and a specialist in the field of welfare work, social insurance and social hygiene.

The Medical Press in Italy

The question of the medical press is being discussed at present in Italy. The excessive number of medical reviews amounting to more than 300, is generally deplored. Some of the journals are merely advertising mediums of pharmaceutical houses; others are in the interest of some form of publicity, still others are personal, being written entirely by a single individual. About a hundred of the journals have real medical importance and of these about thirty are for the publication of the proceedings of academies or medical societies; ten are reviews of a general character, and about sixty are the organs of the various specialties, with an average of two or three reviews for each of the twenty or more special branches of medicine and surgery. According to some it would be well to limit the number of special reviews to one for each specialty. But the proposal does not appear feasible for the reason that there are some specialties (phthisiology, oncology) that have a large number of publications and that would not submit to such curtailment. According to others, the selection will be spontaneous, with the elimination, on the part of the public, of the reviews that present a slight interest. Others propose the organization of an association of the medical press as there is none in Italy at present, urging that such problems could be properly handled by such an association.

Statistics on Cancer

Dr. Corradini of the Clinica medica of Florence has collected statistical data on cancer from the case histories of cancer patients admitted to the clinic during the period 1901-1930. The diagnosis of cancer was made in 340 cases, and the diagnosis was confirmed in each case in which necropsy was possible. As regards sex distribution, 68.3 per cent of the patients were men and only 31.7 per cent were women. This observation is in contrast with the statistics usually given by authors, some of whom report 60 per cent of the cases in women and 40 per cent

in men. But it should be noted that the statistics of Corradini concern an institute of *Clinica medica*, to which no patients with uterine cancer are admitted, they being received at the gynecologic departments, nor any patients with mammary cancer, who are sent to the surgical departments. As to the age of the patients, the majority are mature and none were under 20. It was observed that 15.4 per cent of the patients were under 40 years of age and 84.6 per cent were above that age. The most common site was the digestive apparatus. Of 340 cases, 218 were cancer of the stomach (64 per cent) and 32 were hepatic neoplasia. Of the 218 cases of cancer of the stomach, 158 or 72.48 per cent, were in males, and 60, or 27.52 per cent, were in females. Of these patients, 84 per cent were above 40 years of age, while 37.5 per cent were under 50, and 62.5 per cent were above 50 years of age.

Treatment of Thrombophlebitis with Roentgen Rays

Prof. Dr. T. Halban, head of the gynecologic department of the Wiedener Hospital in Vienna, presented recently, before the Wiener Gesellschaft der Aerzte, a number of patients who had been treated by roentgen rays after his new method, as a cure for thrombophlebitis. Encouraged by the results secured in other inflammatory conditions, Halban employed roentgen rays in all cases of phlebitis occurring in his department, the whole inflamed area being treated at short intervals with weak erythema doses. Phlebitis, a painful disease which sometimes confines patients to bed for months, often changed its character abruptly. The first sign of improvement is freedom from pain, which follows the treatment almost immediately. The temperature becomes normal in from one to two days, the swelling goes down, and the inflammatory process is checked. In a number of the cases presented, a cure was effected in two days. The results secured with roentgen irradiation in the trial cases have been so satisfactory that this procedure has been employed in the department of Halban in all cases of phlebitis along with other recognized modes of treatment. As the transportation of phlebitis patients to a roentgen laboratory is dangerous, Halban recommends the use of a portable roentgen apparatus in the hospitals, in order that the irradiation may be applied at the bedside.

Radium for the New Cancer Hospital in Vienna

Under the direction of Professor Tandler, who is the head of the Vienna bureau of health, the municipality has decided to spend \$300,000 for the purchase of 5 Gm. of radium. With this purchase Vienna will have secured the same amount of this element that Stockholm possesses, and only one other city of Europe (Paris, 6 Gm.) will have more. The purchase has been under consideration for four years so as to give an opportunity of studying the plan from every angle. Professor Tandler visited the Stockholm Radium hemmet and received from Professor Forsell the director valuable advice and assistance. Two other physicians of Vienna have studied the Stockholm methods on the ground and Professor Forsell has permitted one of his assistants to come to Vienna. In order to carry out as soon as possible the treatment of cancer patients with the new supply of radium, the municipal hospital in Linz, a suburb of Vienna, has vacated a number of rooms for the 'Vienna municipal cancer institute' and in April the institute will begin its activities. The institute will be available not only for the patients of Vienna but for anybody. As Professor Tandler stated when at the last session of the municipal council of Vienna, he made his announcement, the solution of the cancer problem is one of the most urgent needs of medicine. The mortality from neoplasms has reached first place in Vienna and exceeds that of all other causes of death given in the statis-

tics. In a radium institute organized on modern lines, not only early treatment of cancerous conditions, which is so important, can be carried out, but also opportunities are offered for the prompt recognition of such conditions and for the after-treatment following cancer operations. In the present status of cancer therapy, paramount importance is attached to the after-treatment. Immediately after the establishment of the radium institute, it is planned to organize a school in which courses will be given to fit physicians for the work of a radium specialist. There are few genuine radium specialists. Heretofore, radium has been employed chiefly by the surgeons, the gynecologists and the dermatologists. For each case the optimum was left, to a great extent, to chance. Then, the quantity of radium that was available in Vienna was too small to meet the needs. Many, for want of money, were compelled to forego radium treatment. Radium therapy received its first impetus in Vienna. It is well known that the Austrian government, several years ago presented to Madame Curie the 5 Gm. of radium that is now in Paris—at which time it was not as expensive as at present. Vienna will thus soon have two cancer hospitals, one an American foundation (Child Canning's Cancer Hospital Foundation in Vienna), which has been active for the past year and a half but which does not have much radium, and the new municipal radium institute which in fact will be chiefly a cancer hospital and secondarily an institute of research and instruction.

Results of Malariotherapy in Dementia Paralytica

In the Vienna psychiatric clinic where malariotherapy as a form of treatment in dementia paralytica was inaugurated by Wagner-Jauregg, an exact series of statistics on the results of this fever therapy has been preserved and offers excellent material for the study of the problem. From this large series of cases Dr. Dittner, the first assistant of the clinic, selected 129 cases for careful study. These patients received the malarial treatment during the period 1922-1924, so that from six to eight years has since elapsed. His investigations reveal that 67 or more than 50 per cent of the patients, are still living, while the number of permanent cures is surprising. Of these 67 patients 53 are perfectly well. The original fears that the malariotherapy only delays the progress of the disease and that it would later break out anew with greater force have proved to be unfounded. One of the first patients to receive malarial treatment has been free from all symptoms for ten years. Similar results have been achieved in many patients treated since that time. The many patients in whom the progress of the disease has been checked and in whom the condition is stationary must be regarded as cured since the Wassermann test on the spinal fluid has been consistently negative. And even though the malariotherapy exerted no appreciable influence on the clinical picture it has lengthened the life of the patient. The malariotherapy is most effective in combination with arsphenamine in the form of after-treatment. The combined method gives the most permanent cures and the fewest deaths. Of thirty patients who received the combined treatment seventeen are alive after eight years while fifteen have fully recovered, eleven have died, some of them from intercurrent diseases. The results as shown by these statistics exceed the boldest expectations. The large number of permanent cures without remission over a period of from six to eight years of a disease hitherto regarded as incurable and fatal constitutes a triumphant success for malariotherapy. It will be recalled that Professor Wagner-Jauregg, the proponent of this form of treatment was awarded the Nobel prize in medicine for 1927.

Death of Professor Pregl

The death of Prof. Fritz Pregl, the Nobel prize winner in chemistry for 1923 from the effects of a pleuritis occurred recently. For years he was director of the chemical institute

in Graz, after having held a similar position in Innsbruck. Born in 1869, Pregl was the creator of the method of quantitative organic micro analysis, which makes possible complete analyses with only a few milligrams of material for examination. Pregl's new method, together with the use of the micro scale, which he constructed in collaboration with the scale manufacturer W. Kuhlmann, soon became the common possession of the scientific world and yielded unexpected good results. Pregl's method proved to be especially valuable for biologic and physiologic research, since heretofore the lack of material made their solution practically impossible. Pregl introduced also a stable solution of iodine (Pregl's solution), which is well known as a disinfecting fluid. With the passing of this eminent scholar, the world loses a scientist whose activities have exerted an enduring influence.

BERLIN

(From Our Regular Correspondent)

JAN. 12, 1931

Stricter Regulations for Prescribing Opiates

On the basis of section 5 of the opium act of Dec. 10, 1929, the federal ministry of the interior, with the approval of the federal council issued under date of Dec. 19, 1930 a decree that establishes more strict regulations pertaining to the prescribing and dispensing of opiates and cocaine. Medicines that contain these substances may be prescribed only by physicians, dentists and veterinarians and then only on medical indications. Medicines that contain more than one narcotic may not be prescribed, nor medicines that contain coca leaves or preparations of coca leaves or in ester of morphine other than heroin. There is also a prohibition against prescribing various narcotics in substance also against medicines that contain more than 15 per cent of morphine or heroin or the like.

The quantity that may be prescribed for a patient in one day is restricted. If the physician in particular cases wishes to prescribe for a patient in one day medicine that contains more than 2 Gm. of opium or opium preparations or more than 0.2 Gm. of morphine, he must enter notes on the case in a so-called morphine book, including the name, place of residence and age of the patient, and a statement as to what condition necessitates the excessive dose of morphine or opium. He must also state the day on which the prescription is made, the amount of morphine contained in the medicine, and the period for which the medicine is prescribed. Other opiates may not be prescribed at all in these large quantities.

If the medicine is intended for a narcotic addict, the physician must answer in the book a number of special questions. He must enter on the prescription, before his signature, in his handwriting, the words "prescription entered." Also the supply that the physician may secure for his office practice is limited, in other words, he must make the same entries for opium and morphine as have just been mentioned.

Medicines containing cocaine the physician may prescribe for a patient for his own use only in solution and then only in case the purpose intended cannot be attained in any other way. Here, the quantity of cocaine that can be given at one time may not exceed 0.1 Gm. daily. The physician may use medicines containing cocaine only for interventions on the eyes, the larynx, the nose, the ears, the pharynx and the jaws, and then only in case the cessation of pain cannot be accomplished in any other way (up to 1 Gm. daily). Cocaine is thus prohibited wherever it can be replaced by its substitutes. Also for every prescription of cocaine the proper entries must be made in a special book. Further regulations concern the mode of prescribing, for instance the prescription may not be dated back or ahead. The regulations pertaining to the drawing up of the prescription are detailed and precise. Prescriptions that are not made out in accordance with the regulations or that call for undue amounts of a narcotic may not be filled by the pharmacist. However, though a prescription of a physician may

not be made out correctly in every detail, it may be filled provided the bearer of the prescription convinces the pharmacist that an imperative need exists that makes necessary the immediate use of the medicine. In such a case, however, no more of the narcotic may be dispensed than the circumstances justify.

Concerning the medicines dispensed the pharmacist must keep written records which, together with the prescriptions, must be preserved for at least five years. Part of the decree goes into effect February 1 and part of it April 1.

These regulations are intended to curb the increase in the number of addicts since the war, that is, the illegitimate use of these substances. The previous legislation sought merely to provide a supervision of the traffic in substances covered by the opium law and a control of its operation. Thus, the justification for the opium law states that the addiction to a narcotic is often fostered by supplies that are procured from drug stores on the basis of a physician's prescription. Hence, the physicians, dentists and veterinarians had to be included in the group of persons to whom the opium law was immediately directed.

With these regulations, which interfere extensively with the physician's freedom of treatment the government has the means of supervising much more successfully the opium law in the interest of the public health service. At the Danzig medical convention the German medical profession took a hard-nosed attitude in keeping with the purposes of the decree in order that they might lend their support to combating addiction to narcotics. The profession, through its resolution has taken up in a vigorous manner the crusade against narcotics.

The Increase of Influenza

Toward the end of the old year, there were not many cases of influenza, now they are increasing daily. At the Berlin Allgemeine Ortskrankenkasse the number of cases reported daily up to Christmas was about fifty. December 29 the number rose to 109, the day following to 254, and on the last day of the year the 300 mark was passed. During the first days of January the incidence remained about the same. Fortunately the disease still preserves a mild course, though there have been cases with complications, particularly pneumonia, and some have been fatal. Since, at present the number of patients in the hospitals is comparatively small there is a reserve supply of beds. The municipal health bureau is making all necessary arrangements so as to be prepared in case of an epidemic of influenza, that is, as far as Berlin, under present economic conditions, is able to provide.

Institute for Research on Heart Disease

The institute for heart research established in Bad Nauheim through the generous gift of Mrs. Louise G. Kerckhoff of Los Angeles, is nearing completion and can probably be opened the coming spring. The new institute, named after the donor the "Kerckhoff-Institut," will be in charge of Professor Groedel of Bad Nauheim. There will be four departments: a department of examination and diagnosis for patients of the social insurance system, a department for the collection of statistics on the causes of heart disease, a department for public enlightenment as to the causes and the best methods of combating heart disease, and a department for experimental pathology and therapy of heart disease. An administrative council composed of federal representatives, the chairman of the bureau of insurance of Hesse, and representatives of neighboring universities and members of the medical profession will manage the institute.

The Noise in Large Cities

The crusade against the noise of large cities is entering on a new stage after a long period of quiescence (THE JOURNAL, Sept. 27, 1930 p. 949). The Verein deutscher Ingenieure is about to organize on a large scale the crusade against the noise evil. Similar to the organization in New York the work will be divided into sections. The psychologic section will deal

with research on the sources and the varying degrees of intensity of sounds, also on the intensity of tone sensations. A medical section will study the influence of the noise on the nervous system, on the performance of labor and on sleep. A legal section will test the possibility of the law and the police influencing the production of noise, and a technical section will ascertain to what extent the noise of machines and technical apparatus can be reduced and to what extent it is possible to construct machines that are practically noiseless.

Investigations on the effects of noise of various intensities on the hearing, can be made with the means at hand, but there is no method available for the measurement of the subjective sensations or for a comparison of the effects of noise on the individual person. How fruitful such investigations may be is revealed by the fact that with the same physical intensity of sound the tone may under certain circumstances, be perceived ten million times more intensely than under different circumstances.

The thorough scientific manner in which the Verein deutscher Ingenieure is attacking the problem is praiseworthy, yet the question arises whether this thoroughness will unduly delay its practical solution. For the public the sole question is that ways and means may be promptly found to check the persons who produce immoderate noise on the streets, and who are easily recognized, for example, motor cyclists who permit unnecessary gas explosions, the manipulators of auto horns, street car motormen who tear across the switches with a deafening noise and drivers of trucks loosely loaded with rails. The essential work of prevention can be accomplished without scientific research and without interfering in any way with a more scientific study of the problem. The elimination of loud noises in cities is a crying need.

The Cost of Medical Study in Germany

Der deutsche Hochschulfuhrer which is published by the students' association, estimates the approximate cost of medical study, including the cost of living, at 8,600 marks (\$2,046). This estimate allows from 190 to 220 marks for dues and tuition per semester for the five preclinical semesters and from 280 to 310 marks for the six clinical semesters. For dentistry the total costs are only 5,400 marks (\$1,285). The expenditures for the three preclinical and the four clinical semesters are the same as for medicine.

Marriages

EDWIN CROWELL HAMBLIN University Va to Miss Agnes Morton Baptist of Ivy Dec 27 1930

CHARLES P M SHIFFRY Lynchburg Va to Miss Mae Joy Burch of Richmond Dec 31 1930

DAVIS W RITTER, Winchester Va to Miss Lorraine Manger of Reading, Pa Nov 2 1930

VINCENZO E MATULLI Bayonne N J to Miss Sissy Cortese of Naples Italy Nov 15 1930

FRANCIS X KLYNICKI to Miss Halma Regina Raczyński both of Detroit January 6

SAMUEL ROSEN Savannah Ga to Miss Estelle Sawilowski in Augusta Dec 14 1930

JOHN CRABAPPLE PAIMLI Gumer Va to Miss Jane Foster of The Plains January 3

DANON A BROWN Madison Wis to Miss Joyce Ball of Stevens Point, January 3

JULIAN P PIERCE to Miss Clara Hainsworth both of Florence S C February 7

JOHN B OVERALL to Miss Elizabeth Waters both of Springfield, Ky Dec 31 1930

HAROLD B FINCH to Miss Eleanor O'Brien both of Detroit January 18

Deaths

Joseph Phineas Runyan ☉ Little Rock, Ark, Medical Department of the Tulane University of Louisiana, New Orleans, 1890, professor of clinical surgery at the University of Arkansas School of Medicine, member of the American Association of Obstetricians, Gynecologists and Abdominal Surgeons, past president and secretary of the Arkansas Medical Society, past president of the state board of health, and the school board of Little Rock, proprietor of St Luke's Hospital, aged 62, died, February 2, at Hot Springs National Park, of heart disease

Frank Donaldson Moore ☉ Chicago, College of Physicians and Surgeons, Chicago, 1899, formerly associate professor of surgery at his alma mater, member of the American College of Surgeons, vice president and on the staffs of the Garfield Park and Frances Willard hospitals and on the staff of the Mother Cabrini Memorial Hospital, aged 60, died, January 28, of heart disease

Jasper Halpenny, Harlingen, Texas, University of Manitoba Faculty of Medicine, Winnipeg, Manit. Canada, 1900, emeritus professor of surgery at his alma mater, member of the American College of Surgeons, formerly on the staffs of the Winnipeg General and the Grace hospitals, aged 61, died, Dec 19, 1930, of arteriosclerosis and pneumonia

Tecumseh Kingsley Holmes, Chatham, Ont., Canada, Long Island College Hospital Brooklyn, 1865, Medical Department of Columbia College, New York, 1866, Victoria University Medical Department, Coburg Ont., Canada, 1867, past president of the Canadian Medical Association, aged 91, died, Dec 25 1930

William Cowen, New York, Medical Department of Columbia College, New York, 1883, member of the Medical Society of the State of New York, American Otological Society and the American College of Surgeons, on the staffs of the People's and Lebanon hospitals, aged 69, died, January 26, of pneumonia

Richard Griffen Savoye, Westfield N J, New York Homeopathic Medical College and Hospital 1906, member of the Medical Society of New Jersey, president of the board of health of Westfield, aged 49, died January 19 in the Montclair (N J) Community Hospital, of acute myocarditis

Dennis David Crowley ☉ Oakland Calif, Bennett College of Eclectic Medicine and Surgery, 1879, College of Physicians and Surgeons, Chicago 1885, member of the American College of Surgeons, aged 73, died Dec 28, 1930, in the Providence Hospital, of cerebral hemorrhage

John Arthur Ruan, Beacon, Iowa, Central Medical College of St Joseph 1900, member of the Iowa State Medical Society, formerly member and president of the school board, aged 59, died January 12 in the Lutheran Hospital, Des Moines, of pneumonia following an abdominal operation

Sampson Busby Allen, Charlottesville, Va, Bellevue Hospital Medical College New York 1879, formerly on the staffs of the Manhattan Eye and Ear Hospital and the New York Eye and Ear Infirmary New York, aged 77, died, February 4, of cerebral arteriosclerosis

Joseph Addison Patton Stilwell Okla Hospital College of Medicine Louisville 1892, member of the Oklahoma State Medical Association, secretary of the Adair County Medical Society, county superintendent of public health, aged 62, died Dec 5 1930 of nephritis

Benjamin Franklin Wray Camden Ind, Indiana University School of Medicine 1911, member of the Indiana State Medical Association, served during the World War, formerly member of the state legislature, aged 47, died, February 4, of heart disease

Clifford R Spain, Arkansas City Kan, Northwestern University Medical School Chicago 1903, member of the Kansas Medical Society, on the staff of the Mercy Hospital, aged 54, died, January 11, of cardiorenal disease and hypertension

Edward Fenton Cooke ☉ Houston Texas, Fort Worth School of Medicine 1897, member of the Society of American Bacteriologists and the American Society of Clinical Pathologists, aged 55, died January 8, of chronic myocarditis

Jesse W McClure ☉ Milan Ind, Hospital College of Medicine Louisville 1898, Medical College of Indiana University 1904, formerly co-owner of Jennings County and Apple County, aged 65, died January 26, of gastric ulcer

Andrew H Starcke Kansas City, Mo., Kansas City Homeopathic Medical College 1895, member of the Associated Anesthetists of the United States and Canada, aged 56, died February 3, in the Evangelical Hospital, of intestinal obstruction and carcinoma of the colon

Siegmund Albert Reich * Jersey City, N J., College of Physicians and Surgeons Baltimore, 1902, on the staff of the New York Post Graduate Medical School and Hospital, New York aged 52, died February 5, of ungula pectoris

James Nimmo Ellis, Atlanta Ga. Medical College of Virginia, Richmond 1889 member of the Medical Association of Georgia and the American College of Surgeons aged 67, died February 11 of carcinoma of the tongue

William Edward Price, Meredithville Va., University of Virginia Department of Medicine Charlottesville 1882 member of the Medical Society of Virginia, aged 70, died suddenly January 22 of cerebral hemorrhage

Roswell C Basinger * Jackson Miss Tulane University of Louisiana School of Medicine 1923 member of the Medical Association of the State of Alabama, aged 31, died suddenly, January 31 in a local hospital

Carmillus Turner Warner * Marlboro Mass University of Vermont College of Medicine Burlington 1885 aged 66 on the staff of the Marlboro Hospital, where he died January 18 of chronic cholecystitis

Ora George Daniels * Canton Mass Harvard University Medical School Boston 1909 for twenty years senior member of the staff of the Massachusetts Hospital School, aged 53 died February 3 of pneumonia

Bernard Roger Coleman Troy N Y Albany Medical College 1920 member of the Medical Society of the State of New York aged 36 died January 14, of acute uremia acute nephritis and rheumatic fever

Oscar D Swoyer, Allentown Pa University of Pennsylvania School of Medicine Philadelphia 1878 for many years member and president of the school board in South Bethlehem aged 75 died, Dec 19 1930

Frank Salter Nicholson, St Paul Neb Trinity Medical College Toronto Ont Canada 1894 member of the Nebraska State Medical Association, aged 58 died, Dec 10 1930 of carcinoma of the stomach

Ernest Luther Bullard * Rockville, Md Rush Medical College, Chicago, 1883 member of the American Psychiatric Association, aged 71 died, January 17, in Rockingham, N C, of dilatation of the heart

William Dodge, Los Angeles, College of Physicians and Surgeons, Keokuk, Iowa, 1878 past president of the Los Angeles County Medical Society, aged 73 died, January 23 of coronary sclerosis

Walter M Dalbey, Wheeling W Va Baltimore Medical College 1902, member of the West Virginia State Medical Association, aged 56 died, January 9, in San Bernardino, Calif, of pernicious anemia

William Livingston Hartman, Pittston Pa., University of Pennsylvania School of Medicine, Philadelphia, 1866, member of the Medical Society of the State of Pennsylvania, aged 87 died, January 13

Henry D Worth, Bangor, Maine, Medical School of Maine, Portland, 1878, member of the Maine Medical Association for twelve years member of the state board of health, aged 80, died January 26

Ashton Earl Neely * Surg Lieut Commander, U S Navy, Philadelphia Hahnemann Medical College and Hospital of Philadelphia 1915 aged 41, died January 28, in the U S Naval Hospital

Arthur L Fanning, Providence, R I College of Physicians and Surgeons Boston 1907 formerly on the staff of St Joseph's Hospital aged 54 died, January 11, of pulmonary tuberculosis

John W Donges Camden N J University of Pennsylvania School of Medicine Philadelphia 1866 member of the Medical Society of New Jersey aged 86 died February 5, in Miami Fla

Richard Ridgley Lytle New York University of Virginia Department of Medicine Charlottesville 1877 aged 78, died January 31, in St Luke's Hospital, of carcinoma of the small intestine

Canning T Bell De Kalb Miss Memphis (Tenn) Hospital Medical College 1901, member of the Mississippi State Medical Association, aged 52 died, January 26, of heart disease

Lincoln Arden Wheelock * East Cleveland Ohio, Medical Department of Western Reserve University, Cleveland, 1900 aged 65, died, January 24, in Brooksville, Fla, of angina pectoris

Corydon De Kalb Bundy, Kankakee, Ill., College of Physicians and Surgeons Chicago, 1902, aged 58, died, January 12, in Newport Ritchey, Fla, of myocarditis and hypertension

Charles Ives Pegues, Safford Ala., Medical Department of the Tulane University of Louisiana, New Orleans 1893, aged 70, died, January 12, at Dunedin, Fla, of bronchopneumonia

Lawrence George Distler * Middletown N Y, University and Bellevue Hospital Medical College 1899 medical inspector of the public schools, aged 54, died suddenly, January 7

Arthur Lauer, Brooklyn University and Bellevue Hospital Medical College 1911, member of the Medical Society of the State of New York aged 41 died February 3, of pneumonia

Alexander Cromwell Mavety Toronto, Ont., Canada, Queen's University Faculty of Medicine, Kingston, Ont., 1889, aged 78 died Nov 4 1930, in St Joseph's Hospital

Julius Evan Lewis, Washington, D C George Washington University Medical School Washington 1928, aged 31, died Dec 1 1930 while at sea of heart disease

William M Garretson * Anderson Ind Medical College of Indiana 1882 aged 70 died January 27, in a hospital at Indianapolis of cerebral hemorrhage

George Balmer, Toronto, Ont Canada University of Toronto Faculty of Medicine 1898 aged 61, died, Nov 23, 1930 in the Toronto General Hospital

William Jeffries Newbill, Irvington Va University of Maryland School of Medicine, Baltimore, 1868 Confederate veteran aged 84 died Dec 15, 1930

Alfred Gaither, Cincinnati Miami Medical College Cincinnati 1897 aged 67 died January 29, of chronic myocarditis, interstitial nephritis and bronchitis

Frederick W Pulford Detroit McGill University Faculty of Medicine, Montreal Que Canada, 1880 aged 72, died, January 15 in Sandwich Ont

George Winter Whitney New York New York Homeopathic Medical College and Hospital, 1903, aged 51, died, Dec 29 1930 of arteriosclerosis

Charles W Noss * Altoona Pa College of Physicians and Surgeons Baltimore 1907, aged 49, died, Oct 26, 1930 of carcinoma of the colon

Davis Ankeny Dean Pittsburgh, Western Pennsylvania Medical College Pittsburgh, 1891, aged 63, died, January 27, of cerebral hemorrhage

Tillis Gandy * Royce, Miss (licensed Mississippi 1911) aged 45 died January 31 in the Methodist Hospital, Hattiesburg of pneumonia

Willis J Peak, Oakland, Ill St Louis Medical College, 1861 Civil War veteran aged 93 died, January 17, of chronic interstitial nephritis

Charles Eugene Swift * Elkins Ark (licensed, Arkansas 1903) aged 56 died, January 10 of injuries received in an automobile accident

Henry L Older * Morenci Mich Michigan College of Medicine and Surgery, Detroit, 1895 aged 62, died, January 30, of heart disease

Theodore Griffin, Kansas City Kan Cleveland Medical College 1868 Civil War veteran aged 88, died, January 5, of myocarditis

Alson Emery Ingersoll, Fresno, Calif Hahnemann Medical College and Hospital, Chicago, 1871, aged 82, died, Nov 15 1930

Barton S Sheffer, St Joe Ind Cleveland Medical College 1877 aged 83 died January 5 of cerebral hemorrhage

John Charles Drexler, Brandon Minn (licensed, under the Act of 1887) aged 79, died January 22 of arteriosclerosis

John W Mott Los Angeles Rush Medical College Chicago, 1883, aged 88, died, January 23 of chronic nephritis

Charles Robert Oglesby, Bartow Fla, St Louis Medical College 1876 aged 79 died January 16 of heart disease

John William Schmidt Brookview Md (licensed, Maryland, year unknown), aged 82 died, in October, 1930

Bureau of Investigation

MORE MISBRANDED NOSTRUMS

Abstracts of Notices of Judgment Issued by the Food and Drug Administration of the United States Department of Agriculture

Walkers Old Indian Fever Tonic—Bostwick Bros., Atlanta, Ga., shipped in June 1929, into Florida a quantity of Walkers Old Indian Fever Tonic that was declared misbranded. Analysis showed the product to consist essentially of epsom salt, quinine sulphate, a small amount of arsenic, alcohol and water, colored with a pink dye and flavored with oil of cinnamon and other aromatics. The claims that it was a remedy for malarial fever, intermittent fever, typhoid fever, influenza, jaundice, measles, etc. were declared false and fraudulent, and in September, 1929 judgment of condemnation and forfeiture was entered and the court ordered that the product be destroyed—[*Notice of Judgment 16939, issued September, 1930*]

Zunical—Antonio A. Zuniga of New York City shipped in February, 1929, into California more than a hundred bottles of Zunical, which were declared adulterated and misbranded. Analysis showed the product to consist essentially of eggs, creosote, copra, sugar and water. The product was declared adulterated because of the claim on the package that the preparation was antiseptic, when it was not the curative claims, to the effect that it was a remedy for asthma, bronchitis, influenza, whooping cough, etc., were declared false and fraudulent. In August, 1929 judgment of condemnation and forfeiture was entered and the court ordered that the product be destroyed—[*Notice of Judgment 16942 issued September, 1930*]

C C T Antiasthmatic (Hare)—The Shores-Mueller Company, Cedar Rapids Iowa, shipped in July, 1929 a quantity of C C T Antiasthmatic (Hare) that was declared misbranded. The charge was based first on the fact that while the tablets were claimed to contain 2 grains of potassium iodide, they actually contained less than half a grain, and while they were labeled as containing 2 grains of sodium bromide they actually only contained a little over half a grain. The therapeutic claims, to the effect that it was a remedy for asthma, were declared false and fraudulent. In December 1929 judgment of condemnation and forfeiture was entered and the court ordered that the product be destroyed—[*Notice of Judgment 17074, issued November, 1930*]

Rice's Cough Syrup—The Rice Chemical Company, Greensboro, N. C. shipped in January 1929 into Virginia a quantity of Rice's Cough Syrup that was declared misbranded. Analysis showed the product to consist essentially of extracts of plant drugs, including white pine wild cherry, sassafras and bloodroot, in a mixture of alcohol, glycerin, sugar and water. The claims that the preparation was a remedy for coughs, croup, influenza, whooping cough, etc. were declared false and fraudulent and in September 1929 judgment of condemnation and forfeiture was entered and the court ordered that the product be destroyed—[*Notice of Judgment 16949 issued September, 1930*]

Oxidine—W. S. Kirby, Dallas Texas shipped in June and July, 1929 a quantity of Oxidine and Tasteless Oxidine that was declared misbranded. On analysis Oxidine was found to consist essentially of quinine sulphate (about 2 1/2 grains to the ounce), cinchonine sulphate (about 2 1/2 grains to the ounce), extracts of a laxative plant drug, glycerin, sugar, alcohol and water. The so called Tasteless Oxidine was reported to consist essentially of cinchonidine sulphate, oil of peppermint, sugar, alcohol and water. It was fully and fraudulently represented as a food digester, a liver and kidney medicine, a remedy for influenza and various other conditions. In December 1929 judgment of condemnation and forfeiture was entered and the court ordered that the product be destroyed—[*Notice of Judgment 17077 issued November 1930*]

Glykeron—Iglesias and Company, New York shipped in April, 1929, to San Juan Porto Rico, a quantity of Glykeron that was declared misbranded. Analysis showed the product to consist essentially of codine phosphate, an ammonium salt, extracts of plant drugs, glycerin, alcohol, sugar and water. The claim that it was a remedy for coughs, bronchitis, pneumonia, whooping cough, asthma, etc., was declared false and fraudulent, and in February, 1930, judgment of condemnation and forfeiture was entered and the court ordered that the product be destroyed—[*Notice of Judgment 17078, issued December, 1930*]

Vicine—The Vicine Products Company, Memphis, Tenn., shipped in July, 1929, a quantity of Vicine that was declared misbranded. Analysis showed the product to consist essentially of iron sulphate, small amounts of phosphates, calcium salts and sulphuric acid in water. It was labeled as a 'powerful germicide,' when, as a matter of fact, bacteriological examination showed that it was not germicidal. The curative claims, to the effect that it was a remedy for rheumatism, neuritis, bedwetting, sluggish liver, intestinal trouble, cramps, ptomaine poisoning, pimples, halitosis, and dandruff, were declared false and fraudulent and in December, 1929, judgment of condemnation and forfeiture was entered and the court ordered that the product be destroyed—[*Notice of Judgment 17077, issued December 1930*]

Neo-Syn—The Neo-Syn Company of Minneapolis shipped in December, 1928, into Wisconsin 360 boxes of Neo-Syn which were declared misbranded. Analysis showed the product to contain acetphenetidin (phenacetine), aspirin, caffeine and starch. The claim that Neo Syn was absolutely safe was declared false and misleading, furthermore, the declaration of the presence of acetphenetidin was in inconspicuous type and did not include a statement to the effect that acetphenetidin is a derivative of acetanilid. The curative claims that the preparation was a remedy for neuralgia, influenza, headache, periodic pains, etc., were declared false and fraudulent, and in June 1929, judgment of condemnation and forfeiture was entered and the court ordered that the product be destroyed—[*Notice of Judgment 16945, issued September, 1930*]

Bradfield's Female Regulator—The Bradfield Regulator Company, Atlanta, Ga. shipped in June 1929 a quantity of J. Bradfield's Female Regulator, which was declared misbranded. Analysis showed the product to consist essentially of extracts of plant drugs, including a laxative, glycerin, alcohol and water. The claims that it was a remedy for irregularities of the menstrual function and for the treatment of nonsurgical cases of weaknesses and disorders of the female generative organs were declared false and fraudulent and in January, 1930, judgment of condemnation and forfeiture was entered and the court ordered that the product be destroyed—[*Notice of Judgment 17073, issued November 1930*]

Tanna-Menthol—The Tanna Menthol Company, Inc. Enid, Okla. shipped in December 1929 a quantity of Tanna-Menthol that was declared misbranded. Analysis showed the product to consist essentially of potassium iodide, menthol, iodine, tannic acid, glycerin, alcohol and water. The claim that it was a remedy for influenza, sore throat, pyorrhea, etc., was declared false and fraudulent and in February 1930 the court declared the product misbranded and ordered it released to the Tanna Menthol Company, Inc. on the execution of a bond conditioned in part that it be relabeled truthfully and that the company pay the costs—[*Notice of Judgment 17055 issued December, 1930*]

Inhalet—The Iole Manufacturing Company, Middleboro, Mass. shipped in December 1929 into New York a quantity of Inhalet that was declared misbranded. Analysis showed the article to consist essentially of menthol. The claims that the preparation was a remedy for neuralgia, catarrh, influenza, hay fever, asthma, etc. were declared false and fraudulent and in January 1930 judgment of condemnation and forfeiture was entered and the court ordered that the product be destroyed—[*Notice of Judgment 16948 issued September 1930*]

Correspondence

PERINEAL OR "COCCYGEAL" HERNIA

To the Editor —In THE JOURNAL Nov 22, 1930, page 1588, G A Pagenstecher reports a case of "coccygeal" hernia. The anatomic boundaries he gives this hernia are those of posterior perineal hernia.

He also states that 'no case of coccygeal hernia is on record in the present literature.' This statement is incorrect, and if allowed to stand may lead bibliographers into serious error. Though rare there are several cases of posterior perineal hernia recorded in the literature, probably the earliest being Pagen's case described in a letter to Haller in 1750 (Haller *Disputationes chirurgicae selectae* Laussanne 3 313 316 1755). Scarpa described the anatomy of posterior perineal hernia in his monograph *Sull' ernia del perineo* Pavia, 1821.

In 1924 I collected a number of these cases from the literature and made a special study of the anatomy of posterior perineal hernia all of which is described and fully illustrated in my book on Hernia pages 486-498. Piersol's Anatomy gives a brief description of this hernia.

It is unfortunate that this rare and interesting case of posterior perineal hernia should have been reported as a coccygeal hernia.

LEIGH F WATSON M.D. Los Angeles

"PLASTIC REPAIR OF INGUINAL HERNIA"

To the Editor —THE JOURNAL for Nov 15, 1930 contains an article by Joseph A Pettit M.D., Portland, Ore. in which the author states: 'About the time this technique was brought out Skillern presented a plastic flap technique lacking in the essential advantages presented by mine. And on the next page Pettit writes further: I find three distinct disadvantages in the Skillern operation in which the lower or lateral flap is plicated beneath the upper or medial flap: (1) It is not possible to make so extensive a plication, (2) it is not possible to construct a new fascial canal for the structures of the cord without producing an additional curve having a sharp and disadvantageous angulation and (3) the general reconstruction is anatomically incorrect.'

The article describing the operation referred to was published in 1922 (Skillern, P. G. *The Choice of Operation in Inguinal Hernia, Surg Gynec Obst* 34 230 [Feb] 1922) and is quoted by Dr Seward Erdman in the chapter on hernia in Nelson's *Living Surgery* 4 589).

Pettit's article is a discussion of the well known essentials of hernia technique, and his method is a combination of the Bassini and Andrews methods.

In my own article, Tom Jones's illustrations and the legends beneath them (especially figures 2, 3 and 5) show clearly the distinguishing feature of the operation, namely, the approximation and suture of a stout cylinder of aponeurosis-covered musculature (i.e., the rectus edge ensheathed in its fascial coverings) to Gimbernat's and Poupart's ligament. There is now established the strongest possible barrier against recurrence —far stronger than the usually thin and weak conjoined tendon used in the Bassini method. Now, with this as the fundamental barrier, the flaps of external oblique aponeurosis are utilized to take up the strain on the sutures that hold the rectus mass in the concavity of Poupart's ligament rather than of themselves to form a barrier by imbrication, as in the Andrews method, which Pettit uses. Thus, then is my answer to Pettit's first criticism: by plicating the lower flap first I get a firmer grip on the rectus mass to hold it down in place: this is my aim, regardless of the extent of the plication.

As to Pettit's second criticism which concerns the formation of a new fascial canal for the cord my answer is that I don't

form a new fascial canal contrary to his statement, and as to himself practices Skillern, as well as Erdman supports me; thus that the cord interposed between the flaps prevents their agglutination, adding 'Nor is it necessary to cover the cord which, experience has shown, causes absolutely no symptoms when placed in the subcutaneous position.'

As to Pettit's final criticism that the general reconstruction is anatomically incorrect, my answer is, first that I am unaware of any postulates having been laid down the fulfillment of which constitutes an anatomically correct operation for hernia. Secondly, is it possible for a hernia operation to be anatomically correct? And, finally, should an operation that is successful in preventing recurrence of hernia be discarded, even though it is anatomically incorrect?

In my article close study of Tom Jones's illustrations and the legends beneath them will give a clear conception of the technique. I suggest that if the author reviews my operation from this standpoint he will no longer find it, as he writes, lacking in the essential advantages presented by mine.

P. G. SKILLERN, M.D., South Bend, Ind.

THE GRAVES SYNDROME

To the Editor —Your editorial on the Graves syndrome in the issue of Dec 27, 1930 and its criticism by Percy Fridenberg January 31 page 376 merit further comment. Fridenberg asserts that the psychic factor "is certainly not of prime importance and probably not essential to the development of the disease. The emotional symptoms are possibly a result, not a cause of the disease."

The average clinician must heartily agree with the implications in your editorial and with the views of Eli Moschowitz (*The Nature of Graves' Disease Arch Int Med* 46 610 [Oct] 1930) A. S. Warthin (*The Constitutional Entity of Exophthalmic Goiter and So-Called Toxic Adenoma Ann Int Med* 2 553 [Dec] 1928) and others in the opinion that exophthalmic goiter whatever its ultimate cause is a constitutional disorder in which the psyche is of major etiologic importance. Life is too limited to comprehend the ultimate cause of any phenomenon, hence in the investigation of cause we must content ourselves with the limitations of the humanly tangible.

In a paper of ten years ago (*The Psychic Factor in Exophthalmic Goiter, THE JOURNAL*, July 23 1921, p 282) I urged that this syndrome is not goiter and that the sooner this condition is removed from the classification of goiter the sooner will a rationalization of therapeutics be effected. Eight years ago (*The Prevention of Exophthalmic Goiter, Endocrinology* 7 415 [May] 1923) I pointed out that hereditary influences play an important part in susceptibility; that this predisposition may become intensified by factors acquired through errors in the conduct of life or through maladaptation to the world at large; and that in nearly every case of exophthalmic goiter there was superimposed on predisposition an exciting factor usually in the nature of psychic trauma to account for the onset of the syndrome. The following earmarks of susceptibility may be discerned in predisposed individuals: (1) heightened cerebration, asserting itself chiefly in mental alertness and often an aptitude for singular accomplishment; (2) emotional instability expressing itself particularly in deficient inhibition, calm and poise; (3) an excitable heart and labile pulse; (4) vasomotor activity; (5) sparkling eyes which during conversation and active attention may suggest exophthalmos; and (6) undue palpability of the thyroid gland. The most noteworthy characteristic of this class of humanity is a lowered threshold of emotional reaction. In a more recent paper based on a study of 3,343 cases of exophthalmic goiter personally followed up for years (*Psychic Trauma in Pathogenesis of Exophthalmic Goiter Endocrinology* 11 106 [March-April] 1927) I found that at least 2,842 or 85 per cent presented a clear history of psychic

trauma is the exciting cause of the disease. It would therefore appear that the psychic factor plays a major role in the evolution of the Graves syndrome and that this approaches its etiology more closely than any other factor.

ISRAEL BRAM, M.D., Philadelphia

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address but these will be omitted on request.

OCCURRENCE OF EPIDEMIC INFLUENZA IN CYCLES

To the Editor—What are the indications for influenza epidemics this winter? I have read that the disease occurs epidemically in cycles and can usually be predicted in advance. Please omit name.

M.D. Missouri

ANSWER—It would probably be more accurate to say that influenza occurs in 'waves' rather than in cycles. The word 'cycle' is a more specific term than waves and refers to waves that occur in approximately equal intervals of time. Some writers have argued that influenza occurs in a rather short cycle and that when the period for an epidemic falls in the warm weather no epidemic occurs. They thus account for the unequal intervals that occur between epidemics of influenza. The assumption of any length cycle in epidemics of influenza comes far from describing the actual intervals that have occurred between epidemics in past years. Since the pandemic of 1918-1919, which had its major peak in October, there have occurred six fairly definite epidemics that were more or less national in extent. Three of these epidemics had their peaks in February, one in January, one in March and one in May. The years were 1920-1922, 1923, 1926, 1928 and 1929. It will be seen that the times that epidemics have occurred vary both in intervals between the epidemics and in the months in which the epidemic occurs. In view of these facts, it does not seem possible with our present knowledge, to make any prediction as to whether or not an epidemic might be expected in the near future.

Going back to former years, there was a series of epidemics in the decade following 1890 and extending into the first year or two of the next decade. After these epidemics were over there was little indication of excess mortality from influenza for a period of nearly fifteen years, when the epidemics that occurred in the two or three years prior to 1918 began. If the story should be repeated in a similar fashion, we may be beginning on a period when few epidemics will occur, or we may be due for further epidemics in the near future. There seems no basis for telling which will be true, nor, in fact, is there any basis for assuming that the story of the last decade of the last century will be repeated at this time.

STATUS OF VITAGLASS

To the Editor—Kindly inform me as to the present status of Vitaglass. Please omit name.

M.D. New York

ANSWER—Vitaglass is the trade name for one of many patented ultraviolet transmitting mediums that pass ultraviolet radiations more or less freely. Some mediums transmit the radiations better than others. Pure colorless quartz for example is an excellent transmitter of ultraviolet radiation with an efficiency of 92 per cent or more in the therapeutic zone. Common window glass does not transmit ultraviolet radiation in this region.

The therapeutic zone is recognized by authorities as that small band of radiation in the vast electromagnetic spectrum having wavelengths from 2800 to 3100 angstrom units approximately. Authoritative evidence shows that these wavelengths are recognized as effective in preventing rickets and in the activation of ergosterol. This ultraviolet energy is present in sunlight and that reaching the earth in the summer is more abundant than that in the winter.

The Bureau of Standards Research Paper 113 records that vitaglass of thickness 2.5 mm has at a wavelength of 3020 angstrom units an average transmitting efficiency of nearly 25 per cent. More recent tests by the Bureau of Standards (Department of Commerce Bureau of Standards report on solarization of vitaglass letter filed with Council on Physical

Therapy, Sept. 20, 1930) place the transmission efficiency of vitaglass of thickness 2.3 mm after solarization, at 42 per cent. Furthermore, recent tests conducted by the Massachusetts Institute of Technology (Stockbarger, D. C., and Johnson, L. B. Stabilization of Special Ultraviolet Transmitting Glasses Commercially on the Markets, *J. Franklin Inst.* 210:455 [Oct.] 1930) indicated that samples solarized in the same manner had a transmission efficiency as high as 47 per cent at 3,025 angstrom units. The improvement in the manufacture of the product may account for the wide discrepancies in these results, however, the product varies widely from batch to batch.

A recent medical note published in the *Scientific American* (Coblentz, W. W. Ultraviolet Transmitting Glasses, *Abstr. Scient. Am.* December 1930 p. 467) suggested 30 per cent or higher as the minimum efficiency of ultraviolet transmitting mediums at 3,020 angstrom units. Therefore, the purchaser of vitaglass should protect himself by contracting with the dealer to furnish glass whose transmission shall after stabilization of exposure not fall below the efficiency stated.

In a recent test completed by the Detroit department of health (City of Detroit, Department of Health *Weekly Health Review* Oct. 25, 1930) twenty-seven children between the ages of 11 and 14 attended classes in a schoolroom glazed with vitaglass while thirty-six children of the same age studied in rooms glazed with ordinary window glass. The group's score in the vitaglass room was 82.1 whereas the average score of the children in the room glazed with ordinary glass proved to be 82.6. From this investigation it appears that the window glass group had a little of the advantage. If a greater number of children had been examined, however, it is probable that the values would have been nearly the same. In other words there was no indication that children attending rooms glazed with vitaglass were perceptibly improved over those children who attended rooms glazed with ordinary glass.

POMPHOLYX OR RINGWORM DERMATITIS

To the Editor—Is pompholyx contagious? Kindly outline a course of treatment.

M.D. Indiana

ANSWER—A few of the vesicular eruptions on the soles may be due to other causes but authorities agree that most cases formerly called pompholyx are cases of vesicular ringworm dermatitis. They are therefore infectious to a moderate degree. No single plan of treatment will succeed in all cases. Perhaps the best course for the vesicular and bullous cases is to open the larger lesions and apply cool wet dressings of liquor aluminii acetatis diluted with 15 parts of distilled water or saturated boric acid solution. Or the parts may be painted daily with a strong solution (from 0.5 to 1 per cent) of potassium permanganate. Evidence of complicating pus infection (ascending lymphangitis) should be watched for as these vesicular cases afford an excellent atrium for such infections. As the case improves, Whitfield's ointment (6 per cent of salicylic acid and 12 per cent of benzoic acid in petrolatum) or ointment of rosin water may be used in place of the wet dressing or the paint.

Many other methods of treatment are used: tincture of iodine from 3 to 10 per cent ointment of uniodinated mercury (iodine and mercury preparations should not be used at the same time for fear of dermatitis) mercurochrome 220 soluble solution from 2 to 5 per cent x-ray exposures from $\frac{1}{8}$ to $\frac{1}{4}$ erythema dose once a week (irritating drugs should not be used at the same time for fear of dermatitis) chrysarobin ointment from 2 to 5 per cent and many others. The plan mentioned is however the one most often successful to avoid recurrence treatment should be kept up in diminishing intensity for some time after apparent recovery.

PSYLLIUM—PARAPSYLLIA

To the Editor—I note that one of the pharmaceutical houses in the Central West advertises a solution of psyllium seed and petrolatum under the name of Para Psyllia. The formula given is as follows: Liquid petrolatum heavy 80 per cent psyllium seed jelly to make 100 per cent. Does the psyllium jelly have any therapeutic effect?

C. Indiana

ANSWER—The psyllium in this preparation is used simply as an emulsifying agent. It has no more effect on the therapeutic value of this preparation than has the agar in the agar liquid petrolatum emulsions.

In the case of the former the manufacturer informed the A. M. A. Chemical Laboratory that the actual amount of psyllium seed represented in Para Psyllia was less than 1 per cent. In the case of agar liquid petrolatum emulsions analyzed

by the laboratory a few years ago, the average amount of agar found was also less than 1 per cent. In other words these preparations are dosage forms of liquid petrolatum having the advantage of being in the form of emulsions, which are better liked by some than the liquid petrolatum alone.

Pura Psylla has not been accepted by the Council on Pharmacy and Chemistry for inclusion in New and Nonofficial Remedies. The name is not informing of the active ingredient.

STUDY OF POSTPOLIOMYELITIC COMPLICATIONS

To the Editor—In 1887 a woman had an attack of anterior poliomyelitis. She was then 19 years of age. The paralysis affected the lower part of the spine and both legs. There has been a persistent weakness in these muscles with considerable brachice at times almost incapacitating, the patient. Recently there was a severe twinge of pain which seemed to result in a partial paralysis which was only temporary. Her physician diagnosed a stroke. It is my guess that she suffered a subluxation or twist of the weakened spinal column resulting in a temporary inflammatory condition of the cord. Whatever the condition was it has cleared up. There still remains the old postpoliomyelitic weakness of the muscles. Have you any suggestions to offer as to the type of treatment suitable in such a case? Is electricity in any form likely to prove beneficial in a case of forty three years standing?

CHARLES T. SHARPE, M.D., New York

ANSWER—In view of the fact that incomplete data have been given some of the statements in this answer may be irrelevant. If both legs and the lower part of the spine are affected it is evident that a spine brace and two long leg braces should be of value. The spine brace should be of a type known as a corset spine brace, which consists of uprights and pelvic band and crutches for under the arms. The material is canvas with linings in the front or side. The leg braces should have lock joints at the knees and limited joints at the ankles. They may have calipers and they may have a molded foot plate. Massage should be of value. Underwater gymnastics are valuable. Lowman described them in *THE JOURNAL* March 22, 1930 page 845. Muscle training, that is reeducation of weakened muscles is of value. The patient has probably had some of these physical agents. Electricity is of definite value as a muscle tonic in that it maintains the circulation at a high level. Roentgenographic examination should be made of the projections centered over the fifth lumbar vertebra for evidence of spondylolisthesis; that is, a forward slipping of the fifth lumbar on the sacrum. Roentgenograms should also be made of the hips for evidence of partial or complete dislocation.

EFFECTS OF CHLORAL HYDRATE ON CONJUNCTIVA

To the Editor—Some time ago I read in one of the standard authors either H. C. Woods Jr., Bastedo or Cushing on *Materia Medica* that chloral hydrate when used for several days often caused severe pain in the eyes or eyeballs but I have never been able since to locate exactly where I found this information. I have noted its occurrence frequently with patients and I want to confirm this information so I can convince several physicians on the subject. Could you give me this information authoritatively and state where it can be found?

I. F. YOUNG, M.D., Covington, Ind.

ANSWER—Irritation of the conjunctiva is one of the most frequent untoward symptoms of chloral hydrate showing itself in redness and swelling of the conjunctiva, which, however, disappears shortly after the discontinuance of the drug (Lewin, Lewis, *Untoward Effects of Drugs*, Detroit, George S. Davis, 1883, p. 161). Thus, perhaps, accounts for the symptoms observed.

BILATERAL SCIATIC PARALYSIS AFTER CHILDBIRTH

To the Editor—A woman aged about 31 in her second and last labor occurring five years ago suddenly noticed a complete paralysis of both lower limbs. Instruments were used effecting an immediate delivery but the paralysis persisted. I saw her about a month later at which time she had begun to improve. Improvement was gradual but complete after about eighteen months. Now because of the death of the older child she desires to become pregnant and has asked me if there will be any likelihood of the condition recurring during a pregnancy or labor. Her pelvic measurements are normal or possibly a little contracted.

M.D. Iowa

ANSWER—This case is most likely one of bilateral obstetric sciatic paralysis. Only a small number of such cases have been reported in the literature. The cause in nearly all of the reported cases was increased intrapelvic pressure producing trauma to the sciatic nerves. This increased pressure is due to one or more of the following factors: disproportion between the size of the mother's pelvis and the child's head; prolonged

or difficult labor, and instrumental delivery. The symptoms generally appear immediately after delivery but are frequently delayed for a number of days. Both legs are involved and there are both motor and sensory changes. The prognosis is doubtful in most cases. In some instances there is rapid improvement, whereas in others a permanent drop foot remains as a residue. Since the patient referred to made a complete recovery, there is no reason why she should not become pregnant again. The most certain way to eliminate the danger of a recurrence of the paralysis is to perform a cesarean section term but before labor has begun. There is, however, a report of a permanent paralysis which occurred during the sixth month of pregnancy. Since in the present case the paralysis occurred before delivery was accomplished, it would most likely be advisable to deliver the child by the abdominal route at term. An excellent article on this subject is by Samuel Kleinberg in *Surgery, Gynecology and Obstetrics* 45:61 (July) 1927.

ALKALOID IN SUSPENSION RATHER THAN SOLUTION

To the Editor—In Marriott's recent work on "Infant Nutrition," under the subject of rhinopharyngitis the following prescription is given:

Ephedrine (alkaloid)	Gm. or Cc.
Neosolol	0.5
Aqueous dest. q. s.	15
	ad 30.0

As it is my understanding that the alkaloid is insoluble in water, would you kindly advise me how a solution is brought about?

ANGUS B. COWAN, M.D., Fresno, Calif.

ANSWER—In this case the alkaloid is intended to be in suspension, the neosolol favoring this by the gelatin it contains. It is doubtful whether this is a good form in which to prescribe ephedrine, unless used within a short time after preparation. Ephedrine, according to the recent work of Drs. Moore and Moore of Indianapolis, decomposes in presence of moisture and light. Solutions of ephedrine sulphate or ephedrine hydrochloride, however, are apparently stable.

USE OF SUPRARENAL CORTEX

To the Editor—In a case of asthenia with weakness, nervousness and cardiac arrhythmia would the administration of suprarenal cortex be indicated? In what form it is best employed? Would the prolonged use of a salt free diet tend to aggravate the symptoms? Please omit name.

M.D., New York

ANSWER—It is difficult to give a definite answer. Koehler's extract, which has been supplied through the courtesy of the University of Chicago, occasionally has had effect in patients with weakness and nervousness. So far as we know, it has never had any effect in cardiac arrhythmia. The cortical hormone of Swingle and Pfaffner is reported to be specific in its effect and there is no evidence that it would have any effect on this clinical syndrome unless it was associated with Addison's disease or possibly some other endocrine disease. With this combination of symptoms, it might be well to investigate whether there is any evidence of hyperthyroidism. It is extremely unlikely that a salt-free diet could be a factor, unless it interfered with the patient's appetite.

POSSIBLE DIAGNOSIS OF ANEURYSM

To the Editor—A man aged 23, whose work is rapid and strenuous putting in meters has had dyspnea and cough regularly at 4 a. m. for the last four months lasting for half an hour or until considerable expectation takes place. There is some cough during the day which is worse in damp weather. Night sweats exist but no chills or loss of weight. There is no anorexia. His weight is 148 pounds (67 Kg.). He is very tired at the end of a day's work and nervous. Physical examination shows that the lungs are clear, the heart rate is 120 with no enlargement. A systolic thrill is heard at the base of the heart. Blood pressure is 140 systolic and 80 diastolic. Double murmur is heard at the aortic valve and a systolic murmur at the pulmonary area on exercise. The murmurs are loudly transmitted to the carotid arteries. No increased retromammary dullness was found. A fine tremor of the tongue and fingers was observed. The reflexes were hyperactive, the pupils reactant. One blood Wassermann reaction was plus minus. Because two company doctors said he was all right he was not studied again. With this insufficient data can aneurysm give such an interesting chief complaint? If not what? Please omit name.

M.D., New York

ANSWER—From the meager facts given it is difficult to make a correct diagnosis. There are two possibilities. 1. That the patient is suffering from the effects of aortic regurgitation and that his apparent myocardial weakness in the early morning is a manifestation of his lack of reserve in the myocardium. 2. In

spite of the fact that he has lost no weight, hyperthyroidism should be seriously considered. Aneurysm cannot be seriously considered without more data than have been given. A roentgenogram of the chest should also be made and several metabolism studies should be undertaken. In addition the patient should be put to bed for at least a week to see what effect the rest has on his pulse rate.

Rhode Island October Examination

Dr Lester A Round, director of the State Public Health Commission of Rhode Island reports the written and practical examination held at Providence, Oct 2-3, 1930. The examination covered 7 subjects and included 70 questions. An average of 80 per cent was required to pass. Sixteen candidates were examined and passed. The following colleges were represented:

College	PASSED	Year Grad	Per Cent
University of Colorado School of Medicine	(1927)	85.4	
Rush Medical College	(1930)	85	
Boston University School of Medicine	(1930)	83.2	
Harvard University Medical School	(1899)	82.8

Idaho October Examination

Hon F F Jenkins, commissioner of law enforcement of Idaho reports the oral and written examination held at Boise Oct 7 1930. The examination covered 13 subjects and included 130 questions. An average of 75 per cent was required to pass. Four candidates were examined and passed. The following colleges were represented:

College	PASSED	Year Grad	Per Cent
Northwestern University Medical School	(1930)	80	
University of Illinois College of Medicine	(1930)	84	
University of Nebraska College of Medicine	(1929)	79	
University of Oregon Medical College	(1929)	85	

Mr Jenkins also reports 4 physicians licensed by the endorsement of credentials at the same meeting. The following colleges were represented:

College	ENDORSEMENT OF CREDENTIALS	Year Grad	Endorsement of
Rush Medical College	(1929) N B M Ex	(1929)	Illinois
University of Michigan Medical School	(1926)	(1926)	Michigan

Wyoming October Examination

Dr W H Hassed, secretary of the Board of Medical Examiners of Wyoming, reports the written examination held at Cheyenne, Oct 6, 1930. The examination covered 13 subjects. An average of 75 per cent was required to pass. One candidate was examined and passed. The following college was represented:

College	PASSED	Year Grad	Per Cent
University of Oregon Medical School	(1924)	(1924)	84.5

Dr Hassed also reports 4 physicians licensed through reciprocity with other states at the same meeting. The following colleges were represented:

College	LICENSED BY RECIPROCITY	Year Grad	Reciprocity with
University of Kansas School of Medicine	(1923)	(1929)	Kansas
Creighton University School of Medicine	(1929)	(1929)	Nebraska
University of Nebraska College of Medicine	(1929)	(1929)	Nebraska

Nevada November Examination

Dr Edward E Hamer, secretary of the Medical Board of Nevada, reports the written examination held at Carson City, Nov 25, 1930. The examination covered 15 subjects and included 110 questions. An average of 75 per cent was required to pass. One candidate was examined and passed. The following college was represented:

College	PASSED	Year Grad	Per Cent
University of Buffalo School of Medicine	(1923)	(1923)	83

Dr Hamer also reports one physician licensed through reciprocity with another state at the same meeting. The following college was represented:

College	LICENSED BY RECIPROCITY	Year Grad	Reciprocity with
University of Toronto Faculty of Medicine	(1926)	(1926)	Michigan

Book Notices

THE TREATMENT OF ASTHMA By A H Douthwaite M D F R C P Assistant Physician Guy's Hospital Cloth Price, 7/6 Pp 164 London H K Lewis & Co Ltd 1930

The author has endeavored to epitomize the present knowledge of asthma, with especial regard to treatment. This book is intended to help out the recent concerted activities of the Asthma Research Council activities that are arousing the keen interest of many not only in Great Britain and other parts of Europe but also in this country. The author divides asthma into two groups (a) primary, including those patients suffering since childhood and (b) secondary, including those cases which occur after puberty or middle age and follow some respiratory disorder such as influenza. The first type corresponds to our allergic group, or true bronchial asthma. The second includes chiefly the nonallergic or asthmatic bronchitis cases. He pays particular attention to the deformities that arise in chronic cases including emphysema and other chest complications. He lays much stress on Oriel's recent work on isolation from the urine of a protease excreted during an attack in the allergic type of asthma and in many other allergic diseases. This protease when isolated and injected intradermally in minute doses even as low as one part in a million produces a positive reaction; it has no effect on normal individuals nor is an active substance of this nature to be found in their urine. This protease disappears between attacks. As to etiology he is fair and gives allergens local irritants reflex stimulation and psychic influences their proper places. He advocates intradermal tests only if scratch tests are negative. He errs however, in stating that in the case of children it is seldom practicable to perform skin tests because of the fear induced by scalp or hypodermic needle for it is in children that the tests are especially indicated. The remainder of the book is devoted to treatment. The usual drugs are mentioned with the sound advice to avoid morphine unless absolutely necessary. Specific allergic treatment is emphasized and the rarity of cure by major operations. Vaccines are recommended in infectious cases. Physical exercises and massage are stressed at length. A book containing much valuable information.

GRUNDLAGEN UND ENTWICKLUNGSGESCHICHTE DER KINDLICHEN NEUROSE. Von Erich Benjamin. Eine ärztlich-pädagogische Studie. Paper. Price 9 marks. Pp 144 with 5 illustrations. Leipzig: Georg Thieme, 1930.

The author of this little treatise is a children's specialist, not a psychiatrist or a psychologist. He has made his observations at the bedside and in the consulting room. His experience is that of a general practitioner. He believes that the neuroses and psychoses are intimately associated with the constitutional fabric of the individual. He stresses Kretschmer's views, which deal with the relationship of physical type of body and character. He believes that mentality or its perversions like physique and its variations, are to a greater or lesser degree inherited. He has collected a number of typical cases illustrating ties and neuroses, which he describes in effective detail. He studies the period of rebellious stubbornness (trotz periode), which commonly manifests itself about the second year. This is the period when the child begins to recognize to some extent that he must adapt himself in some degree to his environment. He comes in contact with the world and with people. Where the adjustment does not take place readily the child shrinks from his social contacts and seeks to isolate himself or withdraw from the group, and his behavior may become of the infantile or dependent type. He has developed social attitudes which may express themselves in the form of speech disturbances, proxysms of rage, tantrums, anorexia and vomiting. The author bases his observations on the clinical study of 205 children. He believes that every neurosis and psychopathic manifestation has its origin in early childhood. He thinks that the neuroses in boys manifest themselves differently than in girls. In the former it is more common to find some evidence of an arrest of psychic development. Anorexia, sleep disturbances, vomiting and fear occur more frequently in girls than in boys. As a rule the girls made better progress in school than the boys. In contrast to this the boys were restless, presented choreiform symptoms and showed lack of independence, speech difficulties and inability to concentrate. Both boys and girls of this group show lack of confidence and deficiency in initiative. Benjamin is of the opinion that the inferiority complex, physical defects and sexual emotions play a considerable part in the causation of neuroses but are of secondary nature, not primary. Sexuality he thinks, is an expression of the individual's social reaction and the author interprets sexuality in that light. Benjamin emphasizes the importance of early prophylaxis and treatment. Since he maintains that neuroses and psychoses have their origin early in life, the home and the school should combine to give appropriate training and instruction to prevent the formation of nervous habits and tendencies.

TREATMENT OF EPILEPSY. By Fritz B. Talbot, M.D., Clinical Professor of Pediatrics, Harvard University Medical School. Cloth. Price \$4. Pp 308. New York: Macmillan Company, 1930.

This monograph has been written with a great deal of thought toward compiling the various theories regarding the etiology and pathology of epilepsy. A thorough discussion of these phases of the epileptic problem precedes the body of the book, which is concerned with treatment. The author has been known for his consistent and intelligent research on the metabolism of epilepsy and the ketogenic diet therapy in epilepsy. He discusses almost all the modern treatments of epilepsy, including drug treatment and dehydration. His consideration of the technique of the ketogenic diet is masterful and well supplied with practical details. Any one who is concerned with the therapy of epilepsy can secure in this book both a general survey of the field and detailed instructions for the actual technique.

HYPERSENSIBILITES SPECIFIQUES DANS LES AFFECTIONS CUTANÉES. ANAPHYLAXIE, IDIOSYNCRASIE. Par Pasteur Vallery-Radot, professeur agrégé à la Faculté de médecine, médecin des hôpitaux et Mlle V. Heimann, interne des hôpitaux. Paper. Price 25 francs. Pp 146. Paris: Masson & Cie, 1930.

Mention of the name Vallery-Radot gives assurance of the value and dependability of this book. The book is written in Vallery-Radot's simple, clear, readable style which makes it equally useful to specialists and to general practitioners. They give an interesting review of the experimental phases of anaphylaxis, take up the clinical phases of the subject including diagnostic methods and, finally, show the relationship of various

dermatoses such as urticaria, angioneurotic edema, eczema, erythema, pruritus and prurigo to hypersensitivity to foreign matter. They believe that before a skin disorder can be classified as definitely allergic in origin, it should be proved to be due to sensitivity to foreign material. They think that such a conclusion should not be based on the mere finding of an eosinophilia or through obtaining relief by so-called shock therapy. They do not include sensitivity to the action of physical agents in this study, although they recognize its practical importance.

INSTITUTE OF INTERNATIONAL EDUCATION. ELEVENTH ANNUAL REPORT OF THE DIRECTOR. SOME REFLECTIONS ON AMERICAN EDUCATIONAL INSTITUTIONS ABROAD. INSTITUTE ACTIVITIES. Paper. Pp 22. New York: Institute of International Education, 1930.

This bulletin contains the eleventh annual report of the director of the Institute of International Education. It outlines the activities of the institute during the past year in fostering friendly international educational and cultural relations between the United States and Europe, Latin America, the Near East and the Far East. Lists of visiting scholars, publicists, teachers and journalists are included. The report is supplemented by statistical tables of foreign students in American colleges and universities, the distribution of foreign students by institutions in the United States, and a statistical summary by countries of foreign students in the United States.

TECHNIQUES HISTOLOGIQUES DE NEUROPATHOLOGIE. Par Jean Bertrand, directeur de l'École Pratique des Hautes Études. Préface du Professeur G. Guillemin. Paper. Price 50 francs. Pp 323. Paris: Masson & Cie, 1930.

The remarkable growth of neurology was unquestionably due mainly to the progress of neuropathology. Clinical observations are especially valuable when supported by pathology. The famous school of French neurologists—Charcot, Raymond, Dejerine, Pierre Marie—always laid stress on pathology, and the present head of the neurologic service at the Salpêtrière, Professor Guillemin, is the most eager follower of the tradition of the French school of neurology. His chief of the laboratory at the Salpêtrière rendered an exceptional service to neuropathology by publishing his book. The methods of neuropathology research, mainly those of staining, became alarmingly numerous and even confusing. Almost every neuropathologist of prominence prefers certain methods or devises methods of his own. For a beginner in neuropathology, and a general pathologist, it is not easy to become oriented in the mass of staining methods recommended for routine or research work. The existing manuals are either too short or one-sided or compiled by persons who have no personal experience with the majority of methods used. These shortcomings are practically eliminated in the book of Bertrand. Himself a brilliant student and contributor to the science of neuropathology, Bertrand had an extensive experience with the numerous methods which he describes in a clear, precise manner. An interesting chapter is devoted to cell studies in infra-red rays and their use in photomicrography of the central nervous system. The book is undoubtedly a valuable contribution and should be in the hands of every pathologist.

PHYSICAL DIAGNOSIS. By Warren P. Elmer, B.S., M.D., Associate Professor of Clinical Medicine, Washington University School of Medicine, and W. D. Rose, M.D., Sixth edition. Cloth. Price \$10. Pp 903, with 337 illustrations. St. Louis: C. V. Mosby Company, 1930.

At the request of the publishers, Dr. Elmer has taken over the task of completely revising Dr. Rose's work on physical diagnosis, which had gone through five editions. Much of the original has been retained, certain chapters have been rewritten, numerous additions have been made and the whole has been rearranged to fit more nearly the needs of medical students. As it now stands, the book is admirably fitted to be used as a textbook for teaching physical diagnosis. The first part is devoted to the technique of complete physical examination of patients, including examination of the abdomen and extremities, as well as special examinations by such physical means as the x-rays and the electrocardiograph. Anatomic landmarks and surface anatomy are well presented. The second part covers the physical diagnosis of diseases of the respiratory and circulatory systems. In many respects the work fills a long felt need in supplying a modern American textbook on physical

diagnosis in which no part of the body is excluded. The work is profusely illustrated, photographs, drawings, roentgenograms and electrocardiograms are used. In the original editions of Rose, many illustrations from other works were freely used in the present volume greater originality is shown, and it is hoped that in future editions much more of originality will be attempted. The volume is appropriately dedicated to Dr George Dock, whose chief interest was the teaching of medical students.

DIE AVERTIN-ANESTHESIE IN DER CHIRURGIE. Von Professor Dr W. Anshutz, Direktor der Chirurg. Klinik Kiel, Dr K. Specht, Assistent der Chirurg. Klinik Kiel und Priv. Doz. Dr Fr. Tiemann, Assistent der Mediz. Klinik Kiel. Paper. Pp 406 60s, with 9 illustrations. Berlin: Julius Springer, 1930.

This monograph of 200 pages comprises 15 chapters with some 60 subdivisions arranged conveniently for reference. A table of contents, an alphabetical bibliography of nearly 400 references, and, in addition, numerous references relating to allied subjects in footnotes. The subjects discussed include (with their subdivisions) the chemistry of Avertin, preparation of the patient, dosage, methods in common use by different surgeons, basal or full narcosis supplementary (inhalation, local) anesthesia, failures, absorption, time of onset of anesthesia, duration and termination of anesthesia, side actions, deaths, and indications and contraindications. The various subjects are not treated with equal comprehensiveness, but the authors have presented a summary of the voluminous literature with clarity, though perhaps from a somewhat too optimistic standpoint. This is illustrated by the fact that while there is a table presenting 103 deaths that have been reported as being due to "Avertin" (not always so considered by the operator) they exclude 74, the authors consider only 12 as certainly attributable to "Avertin" and 17 as questionably so. Every one who has attempted to analyze the reports of deaths due to anesthesia has encountered difficulties that make it impossible to determine the exact number of fatalities, but several who have studied the literature of "Avertin" believe that it has caused more than 29 deaths. There is hardly one of the fifty or more subdivisions relating to the use of "Avertin" concerning which there is not a diversity of opinion. The authors discuss nine types of the more frequently used methods of employing "Avertin," and these do not include the intravenous method suggested by Kirschner, which is also considered separately. The discussion of dosage and that of indications and contraindications with the diversity of opinion show that there is much to learn before the use of "Avertin" can be established on a scientific basis. It is hardly necessary to state that no one should undertake to anesthetize a patient with "Avertin" before he has studied the subject in great detail and with great care and even then one must proceed cautiously until one has acquired experience—after which one will probably be even more cautious.

TECHNIQUE AND RESULTS OF GRAFTING SKIN. By H. Kenneth Christie, M.S. F.R.C.S. Hon. Surgeon, the Hospital Wanganui, N.Z. Cloth. Price 7/6. Pp 67 with 33 illustrations. London: H. K. Lewis & Company Ltd. 1930.

The material forming the basis of this monograph was obtained largely from a series of about thirty cases of skin grafting on chronic ulcers of the leg. In a few instances skin grafting was done on other portions of the body, especially the hands and the face. General considerations including the anatomy are first briefly discussed. The indications for grafting are followed by a discussion of the choice of the Wolff full thickness skin graft, the Thiersch graft and the tubed pedicle grafts with their technique and after treatment. The subsequent history of these grafts on leg ulcers is made possible by a follow-up in about fifteen cases traced two or three years later. It was found in these cases that Wolff grafts were the most satisfactory method of treating chronic ulcers of the leg. The ulcer was excised, including the fibrous base, bone or tendon was exposed if necessary and the full thickness skin graft was placed over and the edges were sutured. It was observed that portions might slough occasionally, but the main mass remained in spite of some infection. Later the remaining raw areas were Thiersch grafted. In a few cases ulcers developed in adjacent areas but the full thickness graft remained intact. The title of the book is somewhat misleading. It should read "Technique and Results of Grafting Skin for Chronic Ulcers of the Leg."

THERAPIE IN EINZELDARSTELLUNGEN. WISSENSCHAFTLICHE GRUNDLAGEN UND PRAKTISCHE ANWENDUNG. Herausgegeben von Prof. Dr R. von den Velden und Priv. Doz. Dr P. Wolff. Insulintherapie einschließlich der Indikationen bei nichtdiabetischen Erkrankungen. Von Prof. Dr E. Frank. Primararzt der medizinischen Abteilung des Stadt-Wenzel-Hancke-Krankenhauses in Breslau und Dr A. Wagner, Sekundärarzt der medizinischen Abteilung des Stadt-Wenzel-Hancke-Krankenhauses in Breslau. Paper. Price 4.80 marks. Pp 99. Leipzig, Georg Thieme, 1931.

This well written monograph gives a brief but systematic survey of the therapeutic uses of insulin. It opens with a brief review of the historical aspects of the subject and the orthodox views as to the physiology of insulin. The discussion of the treatment of diabetes mellitus and diabetic coma is conservative and presents no innovations. Little space is devoted to consideration of dietary measures. As might be expected, the section devoted to synthalin therapy evinces a belief in its efficacy and freedom from danger not shared by all workers in this field. A section is devoted to insulin therapy of nondiabetic conditions. The conditions discussed are underweight and anorexia, parenchymatous liver disturbances, vomiting and dehydration, hyperthyroidism, infections and trophic disturbances. The authors believe that insulin may be of real value in the treatment of such conditions. This section may interest many who find little of particular moment in the first portion of the volume. The appendix contains tables of the composition and caloric value of common foodstuffs, and a basic diet according to Joslin. A subject index completes the volume. As the title indicates, the authors have presented a good bird's-eye view of insulin therapy with little or no attempt to delve into the nature of the conditions treated.

EMERGENCY SURGERY. Volume I. Abdomen and Pelvis. By Hamilton Bailey, F.R.C.S. Cloth. Price \$8. Pp 380 with 324 illustrations. New York: William Wood & Company, 1930.

This book deals with the treatment of urgent surgical conditions affecting the abdomen and pelvis. It is the first volume of a two volume work. Assuming that the diagnosis is made in each case, the author proceeds in the most painstaking detailed manner with the treatment of the condition presented from the indications through the various steps of the operations to the closure of the abdomen including, in most cases, the immediate postoperative care. The dangers and pitfalls that may occur are mentioned and adequate advice given as to how to avoid them. The procedures and operations chosen in each case are standardized, modern and fully described. The book contains a vast amount of reliable information well arranged and stated simply, yet clearly and forcefully. It is interesting to note that transfusions of saline solution, dextrose and blood are extensively used and advised in urgent surgery. The only point on which one may differ with the author is in his treatment of gastric tetany for which, among other things, parathyroid extract is advised but no saline solution. Numerous excellent and lucid illustrations, some of them in color, add enormously to the value of the book and clarity of the text. The bibliography is short, the references being carefully selected and properly limited to the requirements of the average reader. Obviously the author has had an extensive experience with emergency surgery. The teachings embodied in his book will prove valuable to young surgeons and will fill a useful niche in the libraries of those more mature.

EINFÜHRUNG IN DIE PATHOLOGISCHE HISTOLOGIE DER WICHTIGSTEN PULPA- UND KIEFERERKRANKUNGEN, ODER DER HAUTSCHLEIMHÄUTUMOREN DER MUNDHÖHLE. Von Dr Alfred Kuhn. Privatdozent am Zahnärztlichen Universitätsinstitut zu Leipzig. Paper. Price 6 marks. Pp 57 with 4 illustrations. Leipzig: Georg Thieme, 1930.

As stated by Romer in the introduction, this book presents the most important pathologic changes in the teeth and adjacent structures including tumors in the form of characteristic photomicrographs and a short descriptive text. In spite of the high degree of condensation the descriptive matter is clear and well written. The choice of material is excellent and inclusive; the photographs are of a high grade and made from well prepared specimens; the reproductions maintain the same high standard of quality and the paper and printing are of the best. Teacher, student and practitioners can profit from the use of this guide to outline course, to provide suitable illustrations where such material is lacking and to direct the study of prepared specimens.

Emergency Operation Under a Workmen's Compensation Act

(Ocean Accident & Guarantee Corporation v. Lauce (Texas)
25 S W (2d) 665)

An employee, in the discharge of her duties, was struck on the side with a pole. She was operated on for traumatic appendicitis. Thereafter she brought suit to recover compensation under the workmen's compensation act. The jury, on special issues submitted to them found that the appendicitis resulted from the blow, that she was incapacitated, and that she incurred certain expenses for medical services. They found however that before undergoing the operation the injured employee did not request her employer to furnish medical and surgical services. Judgment in her favor resulted, and the insurance carrier appealed to the Court of Civil Appeals, San Antonio Texas.

The insurance carrier contended, among other things, that the operation was performed contrary to the provisions of section 12e of art 8306, Revised Statutes of Texas, which provides that when an employee is injured and a surgical operation will effect a cure or materially and beneficially improve his condition, the employee may demand such an operation. The demand must be made in writing. The Industrial Accident Board must then order a medical examination, and the physician must make a written report. If by the examination report of facts and opinions of experts all reduced to writing and filed with the board, it is shown that an operation is advisable, the board must so state in writing, and on a unanimous order of the board in writing, a copy of which must be delivered to the employee and to the association, must direct the employee at a time and place therein stated to submit himself to an operation for the injury.

While this "red tape," said the court, is being wound and unwound, the spirit of the poor employee may have winged its flight to a fairer and better region. In a case of acute appendicitis, as the present case seems to have been, delay is thought to be dangerous in the extreme and an operation swiftly demanded. The tediousness of the Industrial Accident Board and its reports in writing, slow and uncertain, are placing the life or death of the employee at stake and, like unto the English "Circumlocution Office" so graphically described by Charles Dickens in his "Bleak House," are hanging the employee in the dreadful balance between two eternities. No law can enforce such an absurdity against a human being. The injured employee was in a hospital suffering from an infection which threatened death. She was in no condition to go through winding mazes of a circumlocution office. In a case of grave emergency, an injured employee should be permitted to recover compensation authorized by the statute, even though the very tedious process set out in the statute for obtaining the services of a surgeon are not complied with. The court was nevertheless of the opinion that there should be clear allegations of the emergency and full proof to sustain the allegations before a recovery should be allowed. As these conditions were not complied with in the pleadings, the judgment of the lower court was reversed and the case remanded.

Failure to Remove Placenta

(McDaniels v. Moth (Iowa) 250 N W 311)

The plaintiff sued the defendant-physician for malpractice. She alleged that when he attended her in childbirth he negligently failed to remove parts of the placenta, which decomposed and caused septicemia. At the conclusion of her evidence, the court directed a verdict in the physician's favor and she appealed to the Supreme Court of Iowa.

Medical experts for the patient, said the Supreme Court testified that septicemia would be the natural and probable result of retention of parts of the placenta and that if the physician had examined the placenta he might have determined approximately whether or not any part of it had been retained. But, said the court, it does not appear that even if he had made such an examination some parts of the placenta might not still have

been retained. If he had discovered that the placenta had not been expelled, he might according to the plaintiff's medical experts, have properly relied on the removal of the debris from the uterus by hemorrhage, which might go on for a week or so. If he had attempted artificial removal of the retained parts of the placenta, he might have exposed the plaintiff to the danger of infection from sources other than the retained placental tissue. The defendant physician, therefore, according to the evidence, was compelled to exercise his judgment. There was no evidence that good practice or ordinary care required him to make exploration and removal, and thereby take the chance of setting up another infection. His failure if there was any, to inform himself adequately did not cause the infection. If he had learned of the retention of a part of the placenta, it does not appear that proper practice and due care would have required him to remove them by artificial means, or in time to prevent infection from the retained tissue. Even if he had by artificial means removed the placental tissue, infection from that act or from some other source might have resulted. Granting that he omitted to make an examination and to remove retained placental tissue, there was no evidence to indicate that he failed in the exercise of the knowledge and care ordinarily exercised by physicians in the same locality or similar localities, or in the exercise of due care. The judgment of the trial court, in favor of the defendant physician, was therefore affirmed.

Workmen's Compensation Acts Infection Under a Callosity Compensable—The claimant operated a listing machine, requiring about 10,000 operations daily. A callosity formed on a finger, and infection developed under the callosity, necessitating an operation and causing permanent disability. Under the circumstances, said the Supreme Court of Tennessee, the employee might well have expected a callosity to appear on her finger tip, as they often do on the finger tips of stenographers and violinists. The appearance of an infection, however, was something fortuitous, not to be expected, an unusual event or result, and therefore accidental. If it be argued that the callosity required too long to develop to be regarded as an accident it may be answered that it is not the callosity but the superadded infection which constituted the injury, and that this manifested itself suddenly. The injury was therefore compensable.—*Scars-Roeback & Co v. Starnes* (Tenn.) 26 S W (2d) 128.

Current Medical Literature

AMERICAN

The Association Library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL in continental United States and Canada for a period of three days. Issues of periodicals are kept on file for a period of five years only. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

*Thyroid Factor in Dementia Praecox. R. G. Hoskins and F. H. Sleeper. Worcester, Mass.—p. 411.

Thyroid Factor in Dementia Praecox.—Among 130 subjects of dementia praecox reported on by Hoskins and Sleeper a group of 18 were diagnosed as suffering from thyroid deficiency. Of these, 16 received thyroid treatment. Significant mental improvement followed in 14, or 88 per cent of the cases and 5 patients became well enough to go home. In a control group of 41 patients receiving similar treatment, the incidence of significant improvement was 34 per cent. There was probably some degree of thyroid deficiency in various subjects of the control group since 31 were recorded as showing "endocrine deficiency unclassified." A considerable number of the control subjects received other than thyroid medication, which probably contributed to the improvement shown. In general cases presenting a favorable initial prognosis were excluded from treatment. The results of the study are interpreted as indicating that thyroid deficiency plays a significant part in more than 10 per cent of state hospital cases of dementia praecox and that in properly selected cases thyroid medication in adequate dosage and for a sufficiently prolonged period results in significant improvement. On the other hand relatively little success is to be anticipated from thyroid medication in cases selected at random.

Anastomosis of Nerves.—Ballance relates the results of experiments in which the central end of the divided cervical sympathetic nerve was anastomosed to the peripheral end of the divided facial nerve and to the peripheral end of the divided hypoglossal nerve. Complete functional and anatomic recovery

of the striated muscles of the face, tongue and depressor muscles of the hyoid bone and larynx were observed. No muscle fibers of the face or tongue muscles or of the sternohyoid or sternothyroid muscles appeared to be atrophied as they should be if a dual innervation was necessary for complete restoration of function. The sympathetic nerve fibers seem to join at the anastomoses with the larger cranial nerve fibers and there is no evidence in the microscopic sections that they continued into the cranial nerve trunks. Ballance inclines to the belief that these experiments give support to the view that the anatomic and functional perfection of striated muscle depends on a dual innervation.

Pathologic Changes in Paralysis Caused by Drinking Jamaica Ginger.—Four cases of poisoning with commercial extract of Jamaica ginger are reported by Vonderahe. One case is reported in detail. This case was uncomplicated by other pathologic factors and involved death by ascending paralysis and bulbar involvement. The pathologic studies revealed degenerative changes in the radial and anterior tibial nerves, degenerative changes in the anterior roots, and marked pathologic changes in the anterior horn cells, characterized by swelling, chromatolysis, eccentric nuclei and death of the cells, and occasionally by shrinking of the cells. Central chromatolysis was the predominating type of cell change. All sections showed infiltration with amyloid bodies. The sensory nuclei were only slightly affected. The fiber tracts of the brain stem and spinal cord remained unaffected. Severe cellular changes, similar to those found in the anterior horn cells, were noted in the hypoglossal nucleus and the dorsal motor nucleus of the vagus and nucleus ambiguus. There were no pathologic signs of inflammation, no phagocytic glia cells, lymphocytes, polymorphonuclear leukocytes or endothelial cells. The pathologic observations suggest a toxin which reaches the peripheral nerves in the extremities through the circulation but which subsequently travels into the central nervous system along the nerve fibers and anterior roots. Thus, in addition to the central chromatolysis in the motor cells of the anterior horn associated with involvement of the peripheral nerve, diffuse chromatolysis and death of the cells also occur. The toxin, in severe cases, may then make its way to the medulla where involvement of the vagal nuclei produces death by bulbar paralysis. There is an obvious tendency of the toxin to exert its pathologic effect most severely on motor cells and fibers. The pathologic observations can hardly be regarded as characteristic of any one toxic agent. They serve to eliminate, however, all possibility of the epidemic being infectious in origin.

Congenital Cerebral Cysts.—Two cases of cysts of the cavum septi pellucidi and cavum vergae are reported by Dandy. In each case the two cavities were continuous. The cysts acted as tumors and caused compression of the motor tracts on both sides. Mental symptoms were decided in both cases. One patient had peculiar epileptic attacks of varying character but indicating bilateral involvement of the motor tracts. Suggestive evidence of intermittent intracranial pressure existed in both instances. The diagnosis of cysts of this type cannot as yet be made by clinical signs and symptoms. The diagnosis is easily made by ventriculography. The ventriculographic picture appears to be pathognomonic. An operation is offered for cysts of this character. One patient was well and apparently normal eight months after operation. His physical and mental status was entirely changed by correction of the underlying cause.

Clinical Syndrome of Corpus Callosum.—Alpers and Grant report five cases involving the corpus callosum. In four of the cases the tumor had spread to the surrounding brain tissue so that more than the corpus callosum was involved. In all five cases the tumor involved the anterior portion of the corpus callosum and the frontal lobe as well. There is a clinical syndrome indicating involvement of this structure. This syndrome is most characteristic when the presenting symptoms include mental disturbances, hemiparesis and motor apraxia. A syndrome with the mental symptoms described and with hemiparesis and apraxia is almost characteristic of involvement of the corpus callosum. Less characteristic, but more indicative of callosal implication if tumor is a syndrome consisting of pronounced mental symptom with drooping of the

hemiparesis. In addition, there may be evidences of increased pressure and dyssynergia. It is hazardous to state that such a syndrome as that last mentioned is characteristic of disease of the corpus callosum, but in the authors' experience the mental symptoms that have been found in cases of tumor of the corpus callosum are so strikingly similar in all cases as to justify the statement that in cases with evidences of increased pressure, with mental signs of apathy, indifference, lack of concentration, change in personality and occasionally psychotic manifestations, occurring in the presence of a hemiparesis or even without, a tumor of the corpus callosum should be strongly suspected. The probabilities are that in such cases a tumor will be found in this location.

Arsenic in Spinal Fluid—Cornwall et al. conclude from their study that the favorable clinical results that have been reported in neurosyphilis as a result of treatment with trypan-blue must be ascribed to factors other than the actual quantity of arsenic that enters the spinal fluid.

Manic-Depressive Psychosis—Four hundred and eighty-five cases of extramural manic depressive psychosis were studied by Paskind to determine whether or not any correlation existed between familial neuropathic factors and the age of onset, the length of the attacks and the length of the intervals. A rather definite correlation was found.

Experimental Lesions of Brain from Carbon Monoxide—Experiments made by Semerk and Bacon demonstrate that the effect of carbon monoxide varies in different animals; that it is rapidly eliminated by rabbits and guinea pigs, that rabbits are especially resistant to the gas, and that the weight of the animals, the amount of the gas and the manner of administration modify its action. Symmetrical lesions in the brains of the dogs and more rarely in those of guinea pigs and rabbits, lesions resembling those occasionally found in human brains, may be produced experimentally by injecting the gas into the arterial blood stream or by having the animals inhale pure carbon monoxide or illuminating gas. When pure carbon monoxide is injected into the blood stream it combines so rapidly with the hemoglobin that gas embolism does not occur, or at least not with doses such as were injected in these experiments. Ten cubic centimeters of air alone injected into the carotid arteries of dogs causes severe convulsions, is more frequently and speedily fatal than a similar amount of carbon monoxide, and results in fewer gross changes, these being rarely in the basal ganglia.

Argentaffin Tumors of Small Intestine—Four cases of argentaffin tumor of the small intestine (carcinoid) are reported by Ritchie, one with mesenteric and hepatic metastases. A brief review of opinions as to the nature of these tumors is made, and the conclusions drawn are (1) that the nature of the tumors depends on the nature of the chromo-argentaffin cells of the normal intestine not yet understood and (2) that until this point is decided argentaffin tumors must be placed in the same category as basal cell epitheliomas of the skin, with reference to malignancy and general characteristics.

Experimental Subacute Amyloid Nephrosis in Rabbits—A method has been found by Butt to produce amyloid nephrosis in rabbits. The production of the lesion depends on the regulation of the doses of manganese chloride given subcutaneously so as to permit chronic poisoning. The amyloid degeneration is usually limited to the kidneys except occasionally when the spleen in addition to the kidneys may be involved. The identification of this amyloid-like substance as amyloid is

based on its reaction with the stains that are considered specific for amyloid, i. e., methyl violet and iodine.

Variation in Weight of Thyroid Gland and Frequency of Abnormal Enlargement in Region of Chicago—Jaffe asserts that the average weight of the thyroid gland in the region of Chicago is, for white men, 27.4 Gm., for white women, 28.1 Gm., for Negro men 27.4 Gm., for Negro women, 24.6 Gm., for Mexican men, 23 Gm., and for Mexican women, 26 Gm. The greatest weight of the thyroid gland is found in white men between the ages of 20 and 30, in Negro men between the ages of 50 and 60 in white women between the ages of 30 and 50 and in Negro women between the ages of 30 and 40. Diffuse enlargement of the thyroid gland is more common in persons below the age of 50 than in those above this age. It is more frequent in the male than in the female sex. There are no differences in its incidence as between the two races. The frequency of nodose goiter increases with advancing age. It reaches its maximum in white men in the sixth and in white women in the seventh, in Negro men in the sixth and in Negro women in the sixth decade of life. Nodose goiter is more common in females than in males, and there is a greater disposition to it in the white race than in the Negro race. The percentages for nodose goiter are: white male, 30; white females, 44.7; Negro males, 14.5; and Negro female, 25.6. Sixty-nine and three tenths per cent of goiters are nodose. The majority of nodose goiters are of moderate size, weights above 100 Gm. are rare. The nodes are usually small, seldom reaching a diameter above 4 cm.

Peritonitis—Studies made by Melaney et al. showed that the great majority of patients with peritonitis who come to a general hospital have lesions of the appendix. If the inflammation is limited in extent the peritoneal exudate yields few organisms on smear or culture. If the appendix has not perforated, the disease is usually not fatal, whether the appendix is gangrenous or simply inflamed, the course is mild and the patients are able to return home in about two weeks. If the appendix has perforated, the inflammation is frequently extensive, the peritoneal exudate is profuse, and yields great numbers of bacteria of several different species. The disease is frequently fatal, the course is stormy and the patient who survives has to stay in the hospital about twice as long as if it had not perforated. In gangrene of the appendix there was no evidence from an examination of the peritoneal fluid that the spore-forming anaerobic bacteria either pathogenic or non-pathogenic, are particularly active. Perforative lesions of the small intestine promptly gave severe symptoms. Perforative lesions of the large intestine caused symptoms to develop more slowly and in spite of the fact that they occurred in older people and that more bacteria were found both in smear and in culture, including *Clostridium welchii*, which was invariably present, the large majority of these patients, four of five, recovered. Perforative lesions of the gallbladder were always fatal. Without respect to the cause of the peritonitis in three fifths of the patients coming to the hospital within twenty-four hours in our series the lesion was local, the symptoms were mild, the peritoneal exudate was not profuse, and organisms were rarely seen in smear or obtained in culture. Diffuse peritoneal inflammation was rarely found in cases with symptoms of less than twelve hours duration, but usually in later cases. The

cases with diffuse peritonitis were more severe the peritoneal fluid was profuse, and usually many organisms were seen on smear and recovered in culture. Complications were frequent, and a third of the patients died. When abscesses had formed the history was usually of long duration, although symptoms were moderately severe and there was much thick fluid containing many organisms, both on smear and on culture. The mortality was just half that of the diffuse group. Smears of the peritoneal fluid made at the time of operation and compared with the culture seemed to be of real prognostic importance. When cases of peritonitis were divided into groups according to the number of bacteria that appeared in the peritoneal exudate, it was found that thirty-five cases yielded no organisms, eleven yielded one, fourteen two, fifteen three, nineteen four, nine five, and three six species. In the great majority of cases yielding no growth, the disease was limited to the focus of infection. There were three principal bacterial species of peritoneal exudates. Nonhemolytic *B. coli* was present in 87 per cent of the cases in which bacteria were found; green streptococci were present in 49 per cent, and *C. welchii* was present in 38 per cent. Altogether, twenty-three different bacteriologic groups were recovered. Peritonitis was usually a polymicrobial disease. In only eleven of the seventy-one cases that yielded growth was a single species found. For that reason it was virtually impossible to evaluate the rôle played by each one. There were no fatal cases in the acute local peritonitis group. A third of the cases of acute diffuse peritonitis were fatal. A sixth of the cases of abscess were fatal. All but one of the deaths occurred in cases of perforative lesions in which there was not only a bacterial but a chemical and a foreign body factor. Every case of perforated ileum was fatal and only one of five in the group with perforated colon. Only one patient with a single infecting organism died; that organism was a hemolytic streptococcus. Although a third of the patients were less than 20 years of age, none of these patients died. In the next two decades only three of thirty died. After the age of 40, the mortality increased considerably with age.

Toxin of *Bacillus Welchii* in Toxemia of Acute Intestinal Obstruction.—Thurston failed to elicit any evidence that toxins of *B. welchii* are a factor in the toxemia of acute intestinal obstruction.

Cortical Bone Graft.—Davison and Kraft are of the opinion that an autoplasmic cortical bone graft transplanted aseptically into cortical bone with perfect mechanical adaptation and fixation will heal by primary intention, with preservation of the vitality of the graft.

Vaccination Against Peritonitis in Surgery of Colon.—These studies by Runkin and Borgen emphasize the value of preoperative protection by vaccine against peritonitis in procedures in which resection of parts of the large intestine are involved. It has been amply demonstrated that protection against lethal peritonitis can be established in animals. The relatively transient nature of such immunity is noteworthy. The time element between vaccination and operation is important. The amount of vaccine injected has less significance but is important. The systemic reaction of the patient is often moderately severe but endures only a short period and is never alarming. That the logical preventive reagent is a vaccine prepared from streptococci and colon bacilli is suggested by the predominant presence of these organisms in the exudate in fatal cases of peritonitis and their vast predominance in and around malignant lesions of the large intestine.

Treatment of Fractures of Ankle Joint.—Lorenzetti believes that the closed treatment of fractures of the ankle joint, if properly employed, satisfies all the surgical indications. This statement applies to the more serious malleolar fractures with the marginal fragment at the lower end of the tibia and to those with pluridirectional displacements of the tibiotalus and of the foot. In 435 consecutive fractures of this type observed by him, operation has not been required.

Regeneration of Hyaline Cartilage in Joints.—Experiments have been performed by Shanks on the joints of fourteen dogs to study the regeneration of the hyaline cartilage in superficial and deep defects and on the reaction of this cartilage to direct trauma. The results of these studies show

that hyaline cartilage in joints does not regenerate in less than four weeks. The best evidences of regeneration are found in twelve weeks. Regeneration of hyaline cartilage has been found in superficial defects not involving the subchondral bone. The greatest amount of regeneration, however, is seen in those deep defects which do involve the subchondral bone. Hyaline cartilage is observed to react occasionally to direct trauma with a proliferation of nests of new cartilage cells. No striking difference in the regenerative powers of cartilage in different areas of the knee joint can be demonstrated. No definite evidence of a perichondrium covering the articulating surfaces of hyaline cartilage has been observed.

Tolerance of Normal Subjects to Levulose Factors Influencing Variations in Rise in Blood Sugar.—A metyone levulose tolerance tests and twelve dextrose tolerance tests have been performed by Jolliffe on normal subjects under a variety of conditions. Results have been tabulated according to the fasting blood sugar level. In normal subjects the maximum blood sugar following administration of 30 to 50 Gm (based on body weight) of levulose by mouth rarely exceeds 115 mg per hundred cubic centimeters. A rise in blood sugar to 125 mg or over should be considered an abnormal response to the oral administration of levulose. In the group of convalescent subjects included in this study the levulose tolerance was the same as in the normal subjects studied. Triplicate levulose tolerance tests performed on normal subjects seven or more days apart do not show significant variation in their blood sugar curves. In normal subjects the rise in blood sugar above the fasting level following the oral administration of levulose varies inversely with the height of the fasting blood sugar level. It seems probable that there is a level of blood sugar varying from 95 to 110 mg which, when exceeded, stimulates the sugar storage mechanism to clear the blood rapidly of its excess sugar. A period of ten or fifteen minutes elapses after this excitatory ceiling is reached before the sugar storage mechanism begins to cause a significant fall in blood sugar. The rise in blood sugar above this level depends on the rapidity of absorption of the sugar administered. The rapidity with which the blood sugar falls from its peak probably depends on the glycogen forming ability of the sugar used.

Nucleotide Therapy in Agranulocytosis.—Reznikoff states that nucleotides given intravenously have the power of raising the peripheral polymorphonuclear count in certain agranulocytic conditions. Three patients suffering from agranulocytic anemia recovered after intravenous injections of nucleotides during the course of their disease.

Effect of Overwork on Potassium Content of Cardiac Muscle.—It is believed by Callahan et al. that overwork causes loss of potassium from heart muscle and that this loss is one of the predisposing factors to cardiac rigidity and failure.

Number of Formed Elements in Urinary Sediment of Patients Suffering from Heart Disease.—The number of casts found by Stewart and Moore in twelve hours was usually increased in patients suffering from cardiac disease. In only

the number may be normal. If the average numbers are considered the greatest numbers were passed by those patients suffering from heart failure of the congestive type, the numbers were fewer after recovery and fewer still in those who had never suffered from this illness. Granular casts were frequently found. The number of red blood cells in the urine of patients who had experienced cardiac decompensation was frequently greater than the highest normal value but within the limits in those who had never suffered from heart failure. The average number of red blood cells found in those cases which had never experienced heart failure was twice as great as that in normal individuals in those who were suffering from heart failure or had recovered from it however the average number was from ten to fifteen times as great as in normal individuals. The number of white blood cells was normal in the urine of those patients who had not suffered from heart failure but the average number was approximately twice the average observed in normal individuals. The number was usually within the normal range both during and after recovery from cardiac decompensation, the average number, however, was greater approximately nine and three times, respectively than that in normal individuals the average being less in patients without heart failure than in those who had recently recovered from it and less than in those who were still suffering.

Liver Extract Liver Ash and Iron in Treatment of Anemia—Keefer et al report the results of a study of the effect of feeding liver extract liver ash and iron to patients with various forms of anemia. The following facts were evident. Liver extract was of demonstrable value in increasing the regeneration of hemoglobin in some of the obscure nutritional anemias of childhood, in some of the anemias associated with dysentery in hookworm infestation and in pregnancy. In some cases its effect could be enhanced by iron. Liver ash, when given in amounts that were equivalent to 300 Gm of whole liver, was of little demonstrable value in increasing hemoglobin regeneration. In some cases there was a slight increase in the reticulocytes, hemoglobin and erythrocytes, but the results were never as conspicuous as those obtained with liver extract or large doses of iron. Iron was effective in the treatment of various forms of anemia. Large doses were more effective than small ones. In many instances the effect of iron exceeded liver, liver extract or liver ash, and in some cases a favorable response did not occur until iron was added. When recovery from the anemia followed either liver extract or iron, there was an increase in the reticulocytes of the circulating blood. The lower the erythrocyte count before treatment, the higher were the reticulocytes at the peak of the rise.

Arthritis of Feet—Elliott concludes that painful feet which do not respond to postural treatment are likely to be arthritis with or without manifestations elsewhere in the body. Feet in which the pain is unduly severe may be presumed to be arthritic. Sudden onset of extreme pain in feet should be considered arthritic in origin, and search should be made for the primary focus. Pain in the heel of the so called spur type is in most cases of infectious origin arising from an inflammation of the calcaneal bursa.

Anterior Poliomyelitis in Massachusetts, 1907-1929—Forsbeck and Luther state that in Massachusetts there has been little change in the case rate and mortality rate during the past twenty-three years. The relationship between mortality rate and case rate has not been marked. There is apparently a periodicity in the incidence of poliomyelitis and evidently the fatality rate is higher for years of high mortality. The seasonal distribution for poliomyelitis is similar to that for the U S registration area, the peak occurs in September. There is apparently no relationship between time of the peak and the size of the year's incidence. There is now a tendency for the peak to occur later in the year than formerly. The large number of cases studied shows a ratio of about seventy seven females to every hundred males. This discrepancy is even greater during adolescence. There is a significant relationship between age of incidence and density of population, the cases occurring somewhat later in life in rural communities. However, there is apparently no significant difference in the case rate in rural and urban communities. Since 1918 there has been a striking change in the age distribution of poliomyelitis as a whole. The number of cases in the age group 0-4 has markedly decreased, while there has been a compensatory increase in the relative number of cases in the age group 5-14. The percentage of cases in adult life has remained quite constant.

Early Diagnosis of Pregnancy Zondek-Aschheim Test—Parvey has applied this Zondek-Aschheim test in the study of 191 patients in private practice. The results were in full concordance with the claim of Zondek and Aschheim. In every case the test checked with the clinical observations. In a few instances false reactions were obtained at first but these were regularly proved, on repeated examinations to be the results of error in technique. It has been shown that in the latter months of pregnancy, morning urine must be used because of the diminishing concentration of the hormone at this period. The test becomes negative in abortion and ectopic gestation after separation of the fetus from the maternal circulation.

Effect of Cervical Paravertebral Anesthesia on Pulse Rate During Operations on Toxic Thyroid Gland—Cervical paravertebral anesthesia in addition to anesthetizing the upper cervical nerves, anesthetizes the upper cervical sympathetic ganglion and the upper part of the sympathetic cord. This anesthetization renders the superior and middle cervical cardiac nerves incapable of transmitting to the heart the increased accelerator impulses caused by the hypersensitization of these nerves, and the moderator impulses of the vagus reach the heart opposed only by the accelerator impulses through the lower cervical and upper thoracic cardiac branches of the sympathetic, which are usually not strong enough to overcome the vagus action completely and the pulse rate falls. Consequently, says Brown during the operation of subtotal thyroidectomy for hyperthyroidism cervical paravertebral anesthesia exerts a definite action toward slowing the rate of the pulse. Owing to the fact that under paravertebral anesthesia cardiac shock is less marked, the operative procedure does not diminish the patient's already weakened cardiac reserve and the postoperative course is smoother with relatively less cardiac reaction than with other types of anesthesia.

Perivaginal Fascia in Nullipara—Goff states that in the normal nullipara there is no tissue in the walls of the vagina, urethra, bladder and rectum which can logically be termed fascia, if the classic histologic descriptions of the tissues are observed. There is no fascia between the anterior vaginal wall and the wall of the urethra. There is a thin layer of fascia of the areolar type between the anterior vaginal wall and the wall of the bladder. There is a similar layer of areolar fascia between the posterior vaginal wall and the wall of the rectum. The layer of areolar fascia that separates the anterior vaginal wall from the wall of the bladder (vesicovaginal fascia) and the layer of areolar fascia that separates the posterior vaginal wall from the wall of the rectum (retrovaginal fascia) unite at the sides of the vagina to form the perivaginal fascia, which is a part of the fascia endopelvina. The areolar character of the fascia that separates the vaginal wall from the walls of the bladder and rectum makes it impossible to dissect it as an individual layer, and as such to use it in vaginal plastic operative procedures. If used at all, it must be used in conjunction with the overlying wall of the vagina. There is no fascia other than the areolar perivaginal fascia available for use in the surgical correction of cystocele and rectocele. The successful surgical correction of cystocele, rectocele and urethrocele depends on the utilization of the tissues of the vaginal wall rather than on the use of the fragile areolar fascia that surrounds it. When using the term fascia in descriptions of vaginal plastic operations it is important to stress the fact that the fascia referred to is not of the dense type such as is the sheath of the rectus muscle, but that it is of the loosely arranged areolar type. It is apparent that many gynecologists have applied the term fascia to the muscular coat of the vaginal wall which is situated just beneath the vaginal mucosa because it somewhat resembles a layer of dense fascia in its gross appearance. It is obvious that such use of the term fascia is

not in accord with classic histologic description of the tissues which constitute the vaginal wall. The abandonment of an inaccurate terminology, which is based on the gross appearance of the tissues, and the adoption of one based on the established histology of the tissues in and about the walls of the vagina, urethra, bladder and rectum, will lead to a clearer common understanding of the problems of cystocele, rectocele and urethrocele, and will facilitate the teaching of vaginal plastic surgery.

Graves Constitution—Warthin's and Simpson's theory that in exophthalmic goiter the thyroid gland is not the chief pathogenic factor but an incidental complication and sequela to a constitutional anomaly, is not confirmed by Hellwig's study. The most important histologic criterion of exophthalmic goiter, as far as the thyroid itself is concerned is not the presence of hyperplastic lymph follicles throughout this gland. Of his cases of exophthalmic and toxic goiter only 66 per cent presented lymphoid tissue in the thyroid gland and of the cases without clinical symptoms of thyrotoxicosis 38.5 per cent showed lymphocytic infiltration. In the typical cases of status thymico-lymphaticus, the thyroid gland was free from lymphocytes. Lymphocytic infiltration of the thyroid is not a manifestation of an underlying constitutional anomaly but is a purely local response to hyperplasia and hypersecretion of the gland. Hellwig's observations are in complete agreement with the theory of Moebius that hypersecretion of the thyroid gland is the essential cause of exophthalmic goiter.

Corpus Luteum of Pregnancy—The evidence offered by a case cited by Douglass allows him to state with some assurance that in the human being pregnancy is independent of the hormone supplied by the corpus luteum of pregnancy once its duration exceeds approximately four to six weeks.

Hormone Test for Diagnosis of Early Pregnancy—In Schneider's experience in 100 cases the Aschheim-Zondek test has shown its value effectively in the immediate differentiation of early pregnancy from such conditions as menstrual irregularity due to other causes, delayed return of menses following pregnancy and pelvic masses simulating pregnancy. The rapid disappearance of the hormone after delivery, and the persistence of the reaction following incomplete abortion or death of the fetus, indicate that future investigation may prove the test of value in the diagnosis of retained decidua, tissue following labor or incomplete abortion. The question of the diagnosis of ectopic pregnancy, hydatidiform mole and chorio-epithelioma has not been encountered in this series.

Treatment of Prepatellar Bursitis—Twenty-seven consecutive acute or chronic cases of prepatellar bursitis ("house maid's knee") were studied by Carp to determine the end results of conservative therapy. This consisted in aspiration of the fluid, injection of several cubic centimeters of half strength tincture of iodine into the sac, vigorous massage over the bursa, reinforced adhesive strapping over the sac with the knee in complete extension and the application of a firm pressure bandage over the knee. The cases were preponderant in housewives. About 65 per cent of the patients gave a history of trauma. About one third of the patients complained of pain. Swelling of the bursa appeared either immediately after the trauma or after days, weeks or months. The character of the aspirated fluid depended on the length of time it took for accumulation. In the early cases it was bloody, in the later cases amber or straw colored. Aerobic and anaerobic cultures in eleven cases were sterile. In a little more than half the cases small amounts of fluid reaccumulated in an average time of ten days. Aspiration of this fluid was employed. A second injection of tincture of iodine in these cases was usually not necessary. An average follow up of sixteen months in twenty-four out of the twenty-seven cases showed no symptoms or reappearance of bursal fluid. In twenty of the twenty-four follow up cases the average time for complete disappearance of the fluid was about three weeks.

Ovarian Pregnancy—All of Spiegelberg's criteria were fulfilled in Cranmer's case. The tube on the affected side was intact, the sac occupied the position of the ovary, it was connected to the uterus by the utero-ovarian ligament and ovarian tissue was found completely surrounding the sac.

- *Blood Pressure in Avertin Anesthesia W P Kennedy—p 52
*Influence of Ether on Toxicity of Procaine Hydrochloride R Perez Cordera—p 67

Blood Pressure in "Avertin" Anesthesia—A series of 150 cases of Avertin anesthesia were observed by Kennedy, with especial reference to the changes on blood pressure. These were found to be greater than previously reported and greater than would commonly be considered safe. At the same time no untoward results were observed, and similar changes are reported in young men exposed to very high external temperatures. From the experiences of the series the conclusion is drawn that Avertin provides an advance in anesthetic practice of prime importance.

Influence of Ether on Toxicity of Procaine Hydrochloride—On the basis of experiments on animals, Perez-Cordera states that no alteration in the toxicity of procaine hydrochloride administered intravenously is found if ether is given afterward. A large increase in its toxicity is found if the procaine is administered intravenously after etherization. The increase in toxicity falls rapidly with increase in the time between etherization and administration of procaine. The average fatal dose without ether in mice is 0.09 Gm per kilogram. The average fatal dose with ether is 0.025 Gm. The lethal dose for cats with ether, is about 0.04 Gm. The lethal dose for cats, without ether, is about 0.05 Gm. In cats, intravenous injection of procaine causes a marked effect on respiration which is coincident with a fall in blood pressure. It would appear that ether does not cause any change on the sort of action of procaine.

*One Hundred Cases of Failure of Breast Feeding in First Month H W Pooler—p 269
*Specificity of Hemolytic Streptococcus Associated with Scarlet Fever T Toyoda, J Morioka, Y Futagi and S Hoshizaki—p 282
*Sublingual Mumps with Edema of Tongue J H R Harries and E C Benn—p 293
Pyonephrosis as Complication of Typhoid J Wright—p 296

Postvaccinal Encephalitis in Infancy—A new case of postvaccinal encephalitis in infancy is recorded and twenty one other cases are quoted by Scott. These cases are shown to fall into five clinical groups, whose symptomatology is described. The cerebrospinal fluid is found to be normal in almost every case. There was no particular day after vaccination on which the bulk of cases occurred. The postmortem examination of one case and the typical pathologic picture are described. The differential diagnosis is discussed. The prognosis is shown to depend considerably on the clinical form of the disease. The extreme rarity of this disease in infancy as compared to other ages is illustrated by statistics. The etiology in general is discussed. The relative immunity in infants is discussed and a suggestion is made that family history may be of value in forecasting the liability of the infant to the disease.

Failure of Breast Feeding in First Month—The conclusion Pooler draws from this examination is that the real deciding issue in the whole of these cases was the return of the mother to her domestic duties and worries. There were other conditions which might have caused some trouble but he regards them as auxiliary only in bringing about the early weaning in this group. To some extent he has had to revise the views he expressed in 1928. A longer rest in bed was not effective in three cases. The effects of poor feeding of the mother and the disturbance of the baby's nervous system do not loom large in the analysis. Too frequent feeds seem to be sometimes a result rather than a cause of failure. He does not, however, ignore their influence while stressing the dominant importance of the early return of the mother to her domestic duties.

Hemolytic Streptococcus Associated with Scarlet Fever—From the study of ninety seven strains of these organisms Toyoda et al reach the conclusion that neither morpho-

logically, biologically nor serologically can the scarlet fever streptococci be regarded as possessing a specificity that distinguishes them from other hemolytic streptococci.

Mumps with Edema of Tongue—Harries and Benn report two cases in which solitary sublingual mumps produced a high degree of edema of the tongue. They have not seen the condition before nor have they been able to trace any previously recorded examples in the literature. The tongue of one of the patients was noted to be greatly swollen, protruding from and filling the mouth. The appearance of the tongue was otherwise normal. It was not inflamed but simply much enlarged. When the tongue was raised, the floor of the mouth was seen to be edematous. Both sublingual salivary glands were swollen and tender. There was a moderate amount of enlargement and tenderness of the submental lymph nodes. By exercising considerable pressure on the dorsum of the tongue, it was found to be possible to obtain a momentary view of the palate and fauces. Nothing abnormal was seen. Examination equally difficult, of the buccal mucosa revealed well marked bilateral papillitis of the orifice of Stensen's duct. Similar changes were noted in the other patient.

Treatment of Pernicious Anemia with Hog's Stomach—Wilkinson states that relapses did not occur in any of 108 patients with pernicious anemia treated with fresh and desiccated preparations of hog's stomach tissues. All the patients have done well. This treatment has given highly satisfactory results undoubtedly better than with liver, while the relative effective dose is less than the dose of liver. More than 92 per cent of the patients treated with hog's stomach are perfectly well and the majority are doing their full time work. A further 6 per cent are much improved but still suffer from varying degrees of nervous impairment. Hog's stomach therapy is superior to liver diet in the speed of remission of the condition, the erythrocytes and hemoglobin increasing 157 per cent and 94 per cent respectively, compared with 90 per cent and 77 per cent, respectively with liver under comparable conditions. Clinically, the immediate results are similar to those obtained with liver. They are more prompt and the normal health is reached more quickly, work is resumed sooner and all the gastro-intestinal symptoms appear to be relieved. This is not always the case with liver treatment. Hydrochloric acid and pepsin being frequently required in addition to relieve the indigestion, flatulence and occasional sore tongue. Achylia gastrica persists despite the treatment. Hydrochloric acid and pepsin do not appear to be necessary for the relief of symptoms with this form of treatment. There is a minimum dose of hog's stomach to maintain the normal health of each patient. Regular blood counts are essential for the control of this dose. Fresh hog's stomach can be taken in adequate doses for a few days every three to four weeks with a maintenance of normal health. Several cases with early posterolateral involvement of the spinal cord have shown remarkable improvement, and paresthesias of the hands and feet (with out alteration of reflexes) have been almost completely cured in nearly every case. These have always been the symptoms most resistant to treatment.

- *Local Vascular Changes in Splenic Anemia J McMichael—p 1
Care of Surgical Diabetic A R Gilchrist—p 30
*Dehydration in Intestinal Obstruction G Miller—p 47

Local Vascular Changes in Splenic Anemia—Sixteen spleens from cases of splenic anemia were examined by McMichael. These were principally cases of hepatolienal

fibrosis, but spleens from Egyptian splenomegaly, tuberculosis of the spleen, hemolytic jaundice and some other unclassified types also were examined. In addition, some experimental work has been carried out with regard to obstruction of the splenic vein and the organization of hemorrhages in the spleen. He found that hyaline degeneration of the pulp arteries is a common occurrence after the age of 10 years. It is probably related to involution changes in the lymphoid tissue in the spleen and has no pathologic significance. Endophlebitis of the splenic vein is difficult to detect in its early stages. It is probably determined by raised portal blood pressure, calcification and thrombosis being secondary phenomena. Thrombosis of the splenic vein is not a direct cause of the splenic anemia complex. The siderotic nodules in the spleen are the end-result of periarterial hemorrhages which take origin from the ellipsoidal capillaries. One important factor in the causation of these hemorrhages is congestion of the spleen. This may be determined by arterial hyperemia or by raised venous pressure. It is probable that the periarterial fibrosis of Banti has its origin in the same perivascular hemorrhages. In the cases of hepatolienal fibrosis there was a constant relationship between siderotic nodules and hematemesis. It seems highly probable that both the hematemesis and the siderotic nodules in these cases result from increased portal blood pressure.

Care of Surgical Diabetic Patient.—The nature of the metabolism of the diabetic patient is described by Gilchrist in order to show how acidosis is produced. An improper diet, lack of food, anesthesia and infection all predispose to the production of acidosis. The appropriate treatment and prevention of this condition is outlined. Emphasis is placed on the important part played by sepsis in antagonizing the action of insulin, in precipitating acidosis and in being a frequent accompaniment of diabetic coma. The use of insulin and dietary measures to combat the production and excretion of ketone bodies are described in detail. Postoperative diets that have been found useful in a number of conditions are given. The response of a case of diabetic gangrene to dietetic and insulin treatment is recorded.

Dehydration in Intestinal Obstruction.—Experiments have been carried out by Miller to show the difference in the fluid content of the organs of normal animals and of those dying from intestinal obstruction. On the basis of his observations he asserts that, in high simple obstruction in dogs, death is caused by loss of intestinal secretion causing dehydration and loss of sodium and chloride ions. Only the blood plasma and interstitial fluid are lost. The intracellular fluid is maintained by an ionic concentration consisting mainly of phosphoric acid and potassium. These are not lost in the gastro-intestinal secretion and so dehydration does not impair the intracellular fluid.

*Clinical Conditions Associated with Achlorhydria J F Wilkinson and T H Oliver—p 66

Cranial Blood Pressure Records J F H Dally—p 71

Nembutal as Basal Hypnotic in General Anesthesia I W Magill—p 74

Clinical Conditions Associated with Achlorhydria.—Wilkinson and Oliver assert that they have evidence that an association exists between a gastric secretory disturbance and certain clinical conditions (excluding such well known diseases as pernicious anemia). A hundred cases have been examined and they fall naturally into five groups. Group 1 is a definite clinical entity characterized by gastro-intestinal disturbances and recurrent diarrhea, flatulent dyspepsia and neurasthenia are prominent symptoms. The clinical picture is sufficiently characteristic to allow the diagnosis of achlorhydria to be made with considerable certainty. There were fifty three cases. Twenty five showed achylia gastrica and eighteen hypo-acidity (eight with deficient peptic activity) on examination by fractional test meal. Group 2 comprises twenty five cases in which the prominent feature was a sore tongue or an ulcerative stomatitis. The gastro-intestinal disturbances encountered in group 1 may or may not be present. Fractional gastric analysis showed that nine of these patients had achylia or hypochlorhydria (only one having a normal peptic activity) seven with a normal acidity (four with

reduced peptic activity) and three with hyperacidity. In group 3, five patients complained of skin lesions in addition to the gastro-intestinal or glossitic symptoms, while one other had an urticaria and angioneurotic edema. Achylia was present in four, hypo-acidity in one and hyperacidity in one of the cases. In group 4, five cases of rheumatoid arthritis were examined, one, associated with diarrhea, presented hypo-acidity, while in four with histories of glossitis, three presented achylia and one hypo-acidity. Group 5 comprised ten cases of debility with degrees of secondary anemia, for which no cause could be found. Four patients had achylia and four had hypochlorhydria.

Nontuberculous Tracheal Hemorrhages A Soulas—p 382

Semeiology of Thoracic Pain Pain Provoked by Stomach Syndromes.—After reviewing the literature on the subject, Rist cites personal clinical observations that show the extreme importance of a correct interpretation of the existence of thoracic pain. When such pain is the only symptom, it rarely indicates disturbances in the intrathoracic respiratory organs, on the contrary, it is rather a warning to discard such an interpretation for the thoracic pain that accompanies diseases of the thoracic organs is usually merely one of several more specific symptoms. The monosymptomatic thoracic pain in question is usually a referred pain produced by lesions in other parts of the body, particularly the stomach and duodenum. Among eighty seven cases of thoracic pain of gastric origin observed during one year seventy one times the thoracic pain was localized on the left side. The explanation for this phenomenon is not certain; however, it possesses a certain pathognomonic value in determining the gastric origin of the pain in such cases. The cases observed by the author all concerned patients who had come to the clinic because of a false diagnosis of tuberculosis suggested by the thoracic localization of the pain. In fifty-one of the eighty-seven cases the cause was gastric ptosis, the pain being usually localized in the left interscapulo-vertebral space corresponding to the fifth to the eighth thoracic segments though it sometimes occurs also at the base of the neck and above the infrapinnous fossa toward the anterior portion of the trapezius, the pain being transmitted to the third, fourth and fifth cervical segments by the phrenic nerve. Another important cause of thoracic pain was found to be gaseous distention of the stomach from aerophagy, often caused by swallowing movements made to free the rhinopharynx of pathologic secretions. The pain in such cases is observed in the same region as that produced by gastric ptosis. A third gastric disturbance in which the pain is referred to the thoracic region is medicamentous gastritis. This was especially noticeable in the cases under discussion since in all of them the presence of tuberculosis had been suspected and drugs had often been prescribed that are notably harmful to the stomach, such as creosote, tincture of iodine and various proprietary preparations. The author feels that the facts presented here are sufficient to show how often thoracic pain indicates disturbances in the abdominal organs, especially gastric lesions when the pain is on the left side.

Simultaneous Bilateral Pneumothorax.—Coulaud gives the results in 116 cases in which he used simultaneous bilateral pneumothorax. In 67 cases a unilateral pneumothorax was already present and the second pneumothorax was established after the tuberculous lesions had become bilateral. In 49 cases the double pneumothorax was established from the beginning. Of the 116 patients 67 died and 49 either were living at the time of writing or had died of a disease other than tuberculosis, 19 were definitely cured. Death was due in 4 cases to accidental causes (cardiac disturbances, pneumonia and traumatic perforation) before the pneumothorax treatment was completed. Intestinal tuberculosis was responsible for 14 deaths. The author points out however that this was an additional extrapulmonary localization of the tuberculous condition rather

than an unfavorable result of the pneumothorax. In 49 cases death was the result of the progression of the pulmonary tuberculosis in the collapsed lungs, with or without spontaneous pleuropulmonary perforations or severe hemoptysis. In 28 of the 49 cases the collapse itself was found to be inadequate. Since the collapse was good in all the cases in which the patients were cured it seems logical to conclude that a poor collapse means failure of the treatment. The twenty-one cases in which death occurred from progressive pulmonary lesions in spite of a good collapse present a more serious problem. However, all the 116 cases were severe ones, most of them of long standing and there must necessarily have been a number of patients without sufficient natural resistance to permit of a cure even with the aid of the therapeutic pneumothorax. From his observations the author believes that a bilateral pneumothorax when a unilateral pneumothorax is already established, is indicated beyond a doubt in the presence of cavities in both lungs. Definite contraindications to such treatment are the existence of an imperfect collapse on the side of the first pneumothorax, early bilateral nodular tuberculosis and the existence of a serious extrapulmonary tuberculous localization. Establishment of a simultaneous bilateral pneumothorax at the beginning is indicated in cases of bilateral cavity formation and of involvement of both lungs. It is contraindicated by extensive nodular tuberculosis predominating on one side and by extensive caseous tuberculosis. The author describes the method of treatment used and the complications encountered.

Spontaneous Cure of Tuberculous Pulmonary Caverns—Wohlers points out that the possibility of spontaneous cure of tuberculous pulmonary caverns depends largely on the mechanical conditions governing their evolution. From this standpoint he differentiates the following three classes of caverns as a guide to prognosis and treatment: 1. Caverns of the first class with soft walls, of recent formation, localized in the middle portion of the lung and surrounded by a pulmonary parenchyma only slightly infiltrated, indicate an excellent prognosis and are usually cured spontaneously and quickly by a simple rest cure. A therapeutic pneumothorax is rarely justified in such cases. 2. Caverns of the second class, the walls of which offer little true resistance, of recent formation, localized at the apex or near the hilus, or surrounded by abundant infiltrations, present a less favorable prognosis. The author recommends that a rest cure be tried for at least two or three months. If spontaneous cure does not result, a pneumothorax may then be established. 3. Caverns of the third class with sclerosed walls, formed of a semicartilaginous shell in extreme cases, or of an unfavorable localization at the base of the lung, or of unusual size, generally necessitate surgical intervention according to the exigencies of the particular conditions. The author cites twenty-nine of the many cases of pulmonary caverns on which his conclusions are based.

Antiviral Therapy in Gonococcal Infections A. Bass—p. 1537

Pancreatic Fistula with Reingestion of Pancreatic Fluid and Pancreaticogastrostomy—Cathala and Senéque report a case in which an attack of acute pancreatitis was followed by an adventitious cyst with intracystic hemorrhage. The cyst was punctured and about 4 liters of hemorrhagic fluid was withdrawn. It was then affixed to the abdominal wall by marsupialization. The fistula thus established was well tolerated by the patient for a few days. However, the discharge of pancreatic juice persisted and after a time the patient lost weight and began to grow markedly weaker. Injections of atropine and other medical treatment were of no avail. The

fistula did not heal. A pancreaticogastrostomy seemed advisable but because of the general condition of the patient there was considerable doubt as to the safety of a serious operation requiring general anesthesia. In a day or two the fistula closed and the patient complained of severe pain. Catheterization of the fistula night and morning relieved the pain, the average amount of fluid removed was about 250 cc. For almost two weeks the patient drank each day the pancreatic fluid removed from the fistula. The effects were striking: increase in weight, disappearance of vomiting and digestive disturbances and general increase in physical vigor. A pancreaticogastrostomy was then made with excellent results. The authors feel that the reingestion of pancreatic fluid should be practiced from the first establishment of fistulas of this nature in order to avoid the serious general symptoms that developed in this case. If after four or five months the fistula does not heal spontaneously the patient is then in a proper condition to support an operation.

Antipneumococcal Serotherapy R. Mignot—p. 1630

Absence of Bacteriolytic Properties in Pleural Fluids Discharged in Course of Artificial Pneumothorax—Bezançon and Buc performed a series of experiments to determine whether bacteriolytic properties exist in the fluids discharged in the course of tuberculous pleurisy or in the discharges from artificial pneumothorax. Examination of the discharges from artificial pneumothorax revealed the presence of tubercle bacilli in twenty-two cases out of twenty-four. Inoculation of guinea pigs with these fluids produced tuberculosis in every case. After about two months, however, the virulence of the bacteria was diminished and it finally disappeared entirely. The disappearance of the virulence was not due, however, to the presence of bacteriolytic properties in the fluids, since it was shown experimentally that an emulsion of tubercle bacilli in physiologic solution of sodium chloride, kept in a water bath at a temperature of 37°C, also lost its virulence in about the same length of time. The seemingly curative effect of pleural discharge on tuberculous lesions must therefore be due to some factor other than the presence of bacteriolytic powers in the fluids themselves.

Etiology and Clinical Aspects of Diabetes Mellitus Juvenilis T. Baumann—p. 1129
Syphilis with Resistance to Arspenamine Mercury and Bismuth J. Wyler—p. 1133

Injuries of Eyes Caused by Radiant Energy—Vogt directs attention to the fact that sunlight as well as artificial light under certain conditions may cause temporary or permanent injuries of the eyes. It has long been known that looking

into the sun, which is often done during solar eclipses, is followed by temporary or permanent scotoma. The author found that this injury is mainly due to an injury of the macula lutea by burning of the pigment epithelium and the neuro epithelium by the infra-red rays. Another injury caused by sunlight is the snow blindness developing in the high mountains. This is caused by ultraviolet radiation, which injures especially the corner and the conjunctiva. Glass blowers' cataract, the pathogenesis of which was not entirely clear until recently, is caused by infra red radiation. In regard to roentgen injuries of the eye it is stated that they become noticeable either shortly after the irradiation or after a longer interval. The author advises against the treatment of blepharitis with small doses of roentgen rays because this disturbance usually yields to medicinal therapy, and although roentgenologists assert that small doses of roentgen rays are not injurious to the eye the late effects on the lens cannot be definitely denied. Injury of the eye may also be caused by radium rays. It is similar to that caused by roentgen rays.

Policlinico, Rome

37 521 576 (Nov. 15) 1930 Surgical Section

Obturator Hernia G. Canavero—p. 541
Renal Echinococcus Case L. Mollo—p. 557
Mucocoele and Pseudomyxoma of Peritoneum of Appendicular Origin L. Sussi—p. 568

One Hundred Cases of Perforation of Gastric or Duodenal Ulcer—Barbera describes 100 cases of perforated gastric and duodenal ulcers. In the majority of cases the classic syndrome of acute gastric perforation, the excruciating pain especially in the epigastric region and the marked rigidity of the whole abdominal wall was manifested. Less frequently the secondary signs were noted. In 82 cases of the 100 the diagnosis was accurate, and direct intervention was applied to the stomach. In eleven cases a diagnosis of appendicitis was found wrong at operation. It became necessary to continue the operation higher up when it was found that a gastric lesion was involved. In sixty-nine cases the operation was performed under general anesthesia (in sixty-three cases ether was employed, and in six cases chloroform). In seventeen cases local anesthesia with procaine hydrochloride and morphine was used, and in thirteen cases spinal anesthesia with procaine hydrochloride or tutocain. Xipho-umbilical laparotomy is the preferred form, as it allows the exploration of the stomach and the duodenum and permits the easy execution of gastro-enterostomy. The right transrectal operation is advantageous when the diagnosis 'duodenal ulcer' is assured. There were forty-four deaths and fifty-six recoveries. Of the sixty cases in which the operation was performed within twelve hours, only twelve, or 20 per cent resulted fatally. Of the thirty-five cases in which it was performed between the twelfth and the forty-eighth hour or beyond thirty-one resulted fatally, or 88.7 per cent. All statistics agree in making twelve hours the dead line for a favorable prognosis. Of the three quinquenniums the mortality was 56.25 per cent in the first, 48.2 per cent in the second and 38.6 per cent in the third.

*Prophylaxis of Measles with Normal Horse Serum P. Mazzotti—p. 1049

Electrocardiogram of Healthy Child—Halfer studied the electrocardiographic records of the healthy child in ten boys and girls in the consultation center of the Clinica pediatrica. The youngest was 15 months of age and the oldest 9 years. The records were all taken with the same apparatus (the Siemens in the Clinica medica). From his examination of the records, Halfer concludes that the electrocardiogram of the healthy child is widely differentiated. It presents a progressive

increase of all the positive waves. The P-R interval after the third year of life becomes normal. The deflection R increases steadily until it attains the height observed in the adult. Deflection S is not very deep. Deflection T is variable. In half the cases, and especially in children less than 3 years of age, there was right ventricular predominance, in the others there was an equilibrium between the two ventricles.

Epidemiologic Notes on Acute Anterior Poliomyelitis in Genoa—Magliano, after reviewing rapidly the bibliography of infantile paralysis with regard to the pathologic anatomy, etiology, clinical aspects and epidemiology, describes in a general way 134 cases of poliomyelitis diagnosed in the community of Genoa. He then discusses at length the epidemiology and contagiousness of the disease from various points of view and reaches the following conclusions. Early diagnosis is difficult. It is difficult to determine exactly the period of incubation. He regards the phenomenon of a 'convulsive attack' as a prognostic symptom of grave paralysis or fatal outcome. Slight importance is to be attributed to the economic factor and to the state of nutrition of the patients in relation to the morbidity. The author accepts what has been brought out by other authors with regard to the greater incidence of the disease among males, and in persons of a certain age and at certain seasons. He does not assign much importance as regards transmission of the disease, to animals in general, to blood parasites or to infected objects. Contagion is easy, but the disease is not contracted readily. Great importance is attached to carriers. Absence of multiple contagions in the same family, even in the presence of proved contacts is emphasized. He admits that the virus is introduced through the nasobuccal mucosa or through the digestive tract and accepts the existence of an organic predisposition to the disease.

Still's Disease and Chronic Polyarthritides in Children—Gentili, after general remarks on chronic polyarthritides in children which still constitutes, he admits, an obscure chapter in infantile diseases, describes four cases of Still's disease. This is a peculiar type of chronic polyarthritides in children, especially rare in his region which is always accompanied by enlargement of the spleen a generalized hypertrophy of the lymph nodes and often hepatomegaly. All these symptoms were evident in the four children under discussion. In regard to autonomy of this disease type which is often discussed, he holds that Still's disease from the nature of its peculiar clinical character should be differentiated from the ordinary picture of chronic infantile polyarthritides.

Prophylaxis of Measles with Normal Horse Serum—Mazzotti endeavored to ascertain whether the prophylaxis of measles such as was obtained by Pontano in healthy children by the use of normal horse serum could be secured likewise in sick hospitalized children with a view to arresting a grave hospital outbreak. Two experiments were carried on simultaneously in 1929 in the pediatric clinic and in the Bambino Gesù Hospital in Rome with good results (in the first experiment, about two thirds of the children were exempt while one third exhibited prolonged incubation in the second experiment twenty-four out of thirty-six were exempt, while eight presented prolonged incubation). The partial success attained would have been in all probability total if in place of the small doses employed (from 5 to 7 cc in agreement with Pontano's suggestion) stronger doses had been administered. The author advises further researches in order that the problem of prophylaxis in measles, which is so important for children may be solved.

Cystic Embryoma of Bladder—Castaño says that his case of parasitic teratoma or cystic embryoma of the bladder is the second one reported in the literature. He reviews the genesis of embryonic tumors. His patient, aged 42, while in normal condition, complained occasionally of intermittent disturbances of the bladder associated with hematuria and pain in the perineum. The disturbances followed excessive walking. After one of the attacks the patient while voiding, felt the sensation of having eliminated something. She observed the urine and found an object resembling a small bundle of straw, which proved to be calcified hairs. Roentgen examination showed a pedicled tumor of the bladder. An operation was performed in which the tumor was successfully removed. The anatomicopathologic study of the tumor proved that it consisted of fibrous tissue bones and a papillomatous surface of skin with sebaceous glands in which hairs (like those expelled) were lodged. The lining epithelium of the tumor was ulcerated and the subjacent tissue was infiltrated with lymphocytes and polymorphonuclear leukocytes. There were also pieces of cartilage enclosed in perichondrium and dermis. The author says that in his case the tumor should not be mistaken for a dermoid cyst, in which bones or teeth are enclosed in the cystic cavity. In his case, on the contrary, a layer of skin covered an osteo cartilaginous skeleton, proving that it was a parasite teratoma or cystic embryoma.

Intravenous Quinidine Therapy in Paroxysmal Tachycardia—Padilla and Cossio report two cases of supraventricular paroxysmal tachycardia, one of an auricular and the other of an infranodal origin, in which the intravenous administration of quinidine sulphate suddenly arrested the attacks. The authors conclude that intravenous quinidine therapy is indicated because of its harmlessness in every attack of paroxysmal tachycardia that cannot be arrested by the methods of treatment in common use. The following precautions should be observed in the administration of quinidine. The quinidine sulphate used should be chemically pure with an impurity no higher than 0.5 per cent. The doses should be 0.5 Gm, dissolved in 10 cc of physiologic solution of sodium chloride and as perfectly sterilized as is necessary for intravenous administration. The injection should be given slowly, the patient being placed in a horizontal position. If the dose mentioned does not arrest the attack, a larger dose may be administered, never exceeding a maximum of 0.15 Gm for each 10 Kg of body weight. When the intravenous injection of quinidine causes a cessation of the attack, the drug should be given orally in the usual doses for some time longer, to secure lasting results.

Fibrinopenia in Adult—Jurgens and Trautwein review the three cases of hemorrhagic diathesis with complete or almost complete disappearance of the fibrinogen from the blood reported in the literature and to these add the clinical history of a fourth case the first one ever observed in an adult. Examination of the blood revealed a great deficiency of fibrinogen but a normal amount of all the other components of coagulation. Postmortem examination disclosed an almost completely isolated extensive bone carcinoma with fibrous transformation of the bone marrow. The primary growth was a carcinoma of the prostate. The macroscopic and particularly the microscopic changes indicated that the bone marrow plays a part in the formation of fibrinogen.

Infarct of Myocardium Electrocardiographic Diagnosis—Grotel gives the characteristic changes in the electro-

cardiogram in infarct of the myocardium thus: 1 During the first few days (from one to ten) following complete obstruction of a coronary artery there is an elevation of the R(S)T interval above the iso electric line or a dropping below it with a positive and high T deflection. 2 After from one to ten days there appears a negative deep pointed T deflection preceded by an R(S)T interval with its convexity directed upward thus accompanied by a decrease in the size of the R deflection (in some cases by an increase in the size of the Q deflection). 3 The elevation of the R(S)T interval above the iso-electric line in leads I and II is usually accompanied by its descent below the iso electric line in leads II and III. Usually there appears besides the negative T deflection in leads I and II a positive T deflection in leads II and III. In rare cases there is observed a displacement of the R(S)T interval above or below the iso electric line and the negative T deflection simultaneously in leads II and III. The displacement of the R(S)T interval and the changes in the T deflection in lead II usually repeat the character of the changes either in lead I or in lead III. In angina pectoris without infarct of the myocardium specific changes in the electrocardiogram were not observed. Therefore electrocardiographic examination is of great importance in the differential diagnosis between attacks of angina pectoris caused by an infarct and ordinary attacks of angina pectoris without infarct.

Allergy in Relation to Eosinophilia—Peipers states that in exogenic allergic asthma with positive cutreaction eosinophilia is not always present. It is only one of the clinical manifestations of allergy, and frequently of the predisposition to attacks of asthma. On the other hand, the cutreaction is positive in many clinically latent cases. In persons with a negative cutreaction the presence of eosinophilia indicates that a further search for an allergic etiology should be made with other methods because even in definite allergic diseases that valuable diagnostic symptom may be absent. With the technique used (smear method) an increase in the number of eosinophil cells in the positively reacting skin could not be demonstrated.

Tuberculous Meningitis Glycyltryptophan Test in Cerebrospinal Fluid—From observations in fourteen cases of meningitis, Ammerschlager concludes that tuberculous meningitis cannot be differentiated from other kinds of meningeal inflammation by means of the glycyltryptophan test with cerebrospinal fluid. In basal meningitis the test is definitely positive, but it is also positive in nontuberculous meningitis if it is accompanied by a cell count of at least 500. In such non-tuberculous conditions with an increase in the ferment content of the cerebrospinal fluid a decrease in the intensity of the reaction makes it possible to draw conclusions with regard to the prognosis. In doubtful cases, however, the test is not absolutely reliable.

Concurrence of Cirrhosis of Liver and Gynecomastia—Paula states that, in seven cases of cirrhosis of the liver observed over a period of eight months, gynecomastia was noted five times. His object in reporting the cases is to call attention to the frequent concurrence of the two conditions, because if subsequent investigations disclose changes in the mammary glands in a high percentage of cases of cirrhosis they might lead to important conclusions with regard to either cirrhosis of the liver or gynecomastia.

Fatalities Following Blood Transfusions—Wildegans points out that owing to the great confidence in the reliability of the blood group tests, the number of blood transfusions has greatly increased in recent years. However, in spite of blood group tests, fatalities following blood transfusions are more frequent than is commonly believed. A critical consideration

of the causes of the fatalities shows mistakes that are due to carelessness and that could be avoided, and also those that cannot be foreseen. To the first type of errors belong misunderstandings such as exchanging donors in the event that several transfusions are made at the same time. Fatalities due to errors in the blood group tests can be avoided if a control test is made immediately preceding the transfusion. In order to avoid mistakes in blood group tests, which are caused by deteriorated agglutinating serums, it is advisable to subject these serums to control tests. Before every transfusion the serum of the recipient should be mixed with the erythrocytes of the donor. Occasionally errors in the blood group determination may be due to abnormalities in the blood group. A complication may also be caused when the blood of the donor is not sufficiently diluted in the recipient, this is the case in patients in whom the quantity of blood has been greatly reduced. The total amount of the circulating blood should always be estimated before the transfusion is begun, and not more than one sixth or one fifth of the total quantity of blood should be transfused at one time. Mass transfusions from several donors are likewise not advisable, unless injections with blood diluting fluids have preceded. Endangered by blood from so called universal donors are such persons in whom the blood-forming apparatus is not functioning properly. To detect auto-agglutination, which frequently exists in hemolytic icterus, pneumonia, anemia, cachexia and syphilis, the serum should be mixed with a drop of fresh blood. The phenomenon of panagglutination, which occurs in bacteremia and in chronic suppurations, may likewise prevent a correct determination of blood groups. Death after transfusion is mainly due to the fact that the elimination of the foreign substances overtakes certain organs, such as the kidneys, liver heart and vessels, and causes insufficiency. The danger of thrombosis or of embolism following transfusion is not great, provided the technic is faultless. In some cases it was found that death was caused by dilatation of the heart. Transfusion fatalities are more frequent in diseases of the blood and during sepsis than in acute hemorrhages. In spite of careful examinations, it has happened that malaria and syphilis have been transmitted by blood transfusions. Danger of anaphylaxis exists if in case repeated transfusions are necessary, the same donor is chosen. To avoid this, a new donor of the same blood group should supply the blood. Still under discussion is the relation between agglutination and hemolysis. If hemolysis may take place without a preceding agglutination, then it would be necessary that in the preliminary tests more attention is given to hemolysis than has previously been done.

Artificial Pneumothorax in Treatment of Pneumonia in Infants—In an infant aged 10 months with pneumonia in the right upper lobe an interlobar exudate developed. Duken performed an interlobar puncture and a pneumothorax developed. After that, the child's condition improved rapidly. This unexpected therapeutic effect induced the author to employ the pneumothorax in similar cases. He gives several case reports and thinks that in some instances the therapeutic effect of the pneumothorax was due to the fact that the lung was put to rest in other cases however the good results were due to the changes in the intrathoracic pressure which influence the blood supply. The increased pressure on the side of the pneumothorax

has the effect that more blood enters the healthy lung, and the increased activity of this lung compensates for the insufficiency of the diseased lung, and thus cyanosis is prevented. The author's experiences with pneumothorax therapy of pneumonia in infants and children are limited to eight cases, in which he used this form of treatment in the course of three years. This small number indicates that, in spite of the favorable effects obtained with this treatment, it was employed with great discrimination. In most cases of pneumonia in infants the usual conservative methods are effective. Artificial pneumothorax is advisable in cases of unilateral pneumonia with or without interlobar exudation, which take a protracted course, and which involve the danger of bronch ectasis. It might also be resorted to in order to counteract cyanosis. However, pneumothorax is contraindicated if a unilateral pneumonia of the lower lobes is complicated by a diffuse bronchitis of the other side of the lung. Another contraindication is the presence of thick, suppurative sputum, or of large quantities of sputum because in such instances it is probable that the disturbance involves other conditions besides the pneumonia, and in such cases diathermy has given favorable results.

Pneumothorax Therapy of Pneumonia in Infants—Jahr and Neumann employed artificial pneumothorax in five infants with pulmonary diseases. The authors agree with Duken and other investigators that in some cases this method has therapeutic value. Artificial pneumothorax is indicated in cases of pneumonia with a protracted course and also when pneumonia is complicated with interlobar pleurisy or with mediastinal pleurisy.

Reflexes of Sinus Caroticus During Epilepsy—Marinresco and Kreindler point out that it is generally accepted that an epileptic seizure is related to disturbances in the cerebral circulation. Because the sinus caroticus governs the blood supply of the brain, the authors studied the reflexes of the sinus caroticus on twenty six epileptic patients, by graphically recording the pulse, respiration and the blood pressure, while pressure was exerted on the sinus. To determine the vasodepressor action of the sinus pressure test, plethysmography was employed. On the basis of their observations the authors reach the following conclusions: 1. The reflexes of the sinus caroticus are reduced in epileptic persons. 2. The vasomotor nerves and the blood pressure show a high degree of instability during epilepsy. 3. In some patients especially in epileptic persons, pressure on the sinus may lead to typical convulsive attacks. From this it may be deduced that the sinus caroticus is of great significance in the mechanism of an epileptic seizure.

Treatment and Prophylaxis of Whooping Cough by Means of Vaccine—Kaube reports his experiences with a whooping cough vaccine in an institution for children and nurslings. The preparation that he employed is a vaccine which is injected in increasing concentrations. The number 1 ampules contain 2000 million of *Bacillus hemophilus pertussis*, the number 2 ampules contain 4000 million, the number 3 ampules contain 6000 million and the number 4 ampules contain 8000 million. The injections are made intragluteally at intervals of from three to four days. In the children's department eight or ten children contracted whooping cough. The vaccine treatment had the effect that the sick children improved rapidly so that they were practically cured from ten to twelve days after the first injection. The two other children remained healthy. Of the fifteen nurslings, who likewise received the vaccine two developed a mild form of whooping cough and the others either remained entirely free from it or the infection was so slight that

it was hardly noticeable. The injections were almost painless and did not cause complications such as anaphylactic shock. Even those of the infants and children who developed a slight fever had always a good appetite and were not irritable. The author emphasizes that his experiences with the vaccine are limited to cases in which the whooping cough was in the beginning stage or had not yet begun. He does not know whether the vaccine therapy will have the same favorable effects in a more advanced stage of the disease. However, he recommends its use during the early stage and also for the protection of children who are exposed to whooping cough infection.

Rupture of Uterus Following Incorrect Dosage of Hypophyseal Preparations.—Von Probstner describes five cases of rupture of the uterus caused by incorrect administration of the preparation of the posterior lobe of the hypophysis. Only one of the patients recovered. In this case the rupture had been incomplete. It is emphasized that the ruptures were not caused by the preparation as such but rather by the incorrect administration by giving too large doses, by too frequent administrations or because the preparation was administered at the wrong time or in cases in which it was contraindicated, such as in abnormal presentations of the fetus and in disproportion between the fetal head and the maternal pelvis. The hypophyseal preparations exert the stronger influence the more susceptible the uterus and the farther advanced the process of delivery, namely, during the period of expulsion. They should therefore be employed only during this period. Because the uterine contractions that are produced by the administration of hypophyseal preparations have in the beginning a spasmlike character, they may endanger the life of the fetus. Later they usually become normal, but occasionally the spasmodic labor pains persist and in order to prevent asphyxia of the fetus, the birth has to be completed quickly. However, during the period of dilatation this is not possible without endangering the life of the mother. In regard to the administration of hypophyseal preparations during the period of after-birth, it is stated that some authors have recommended them for every case in order to hasten the expulsion of the placenta. The author however warns against this. He emphasizes that the normal uterine contractions should not be interfered with even if, as the result of overreversion, short intermission set in. The contraction of the uterus should not be accelerated without absolute necessity because this would effect what really should be avoided, namely, atony. Hypophyseal preparations are contraindicated in cardiac and in renal diseases, also in eclampsia and in disproportion between the fetal head and the maternal pelvis. In the conclusion it is pointed out that, if the hypophyseal preparation has been administered, the physician has to remain with the patient until the action of the echolic is completed.

Is There a Thrombasthenia?—Morawitz and Jürgens state that the term thrombasthenia was introduced by Glanzmann, who applies it to a functional deficiency of the blood plates when

they are present in a normal or an almost normal number. However, other investigators have proved that the coagulation of the blood is dependent not only on the presence and the proper function of the blood plates but also on the condition of the vessels, especially the vascular endothelium. A definite demonstration whether a deficient agglutination capacity of the platelets is possible when their number is normal can be made only if the variable vascular factor can be excluded. Up to now there was no reliable method to accomplish this. However, the authors constructed a special apparatus, a so-called capillary thrombometer by which it is possible to determine the thrombosis time extracorporeally and independently of vascular factors. In a case of a peculiar hemorrhagic diathesis, a sort of pseudo-hemophilia, it could be shown that true thrombasthenia does occur. It becomes manifest in a deficient agglutination capacity of platelets that morphologically and numerically are normal. By demonstrating the abnormally prolonged thrombosis time in the capillary thrombometer the proof was given that this phenomenon may develop without involvement of the blood vessel.

Voluntary Modification of Sex in Man.—Futh calls attention to Unterberger's article on the voluntary modification of sex in man which was reported in the *Deutsche medizinische Wochenschrift* (56 304 [Feb. 21] 1930, abstr. THE JOURNAL, May 3, 1930, p. 1451). He also cites others who studied this problem. Blum expresses the opinion that Unterberger's results are not accidental and points out that in 1924 he already had called attention to the sex determining action of the vaginal secretion. Then Futh reports his own investigations. In order to determine whether the reaction of the vaginal secretion influences the sex of the child the vaginal secretions of 23 pregnant women were examined. It was found that among those with a strong acid reaction of the vaginal secretion the number of female births was largest whereas among those with a slight acidity or with an almost amphoteric reaction the number of male births predominated. However, it was yet necessary to determine whether the reaction of the vaginal secretion is the same at the time of conception as during pregnancy. Control tests were made after confinement and it was found that the reaction remains about the same. The larger number of male births in case of slight acidity or in an almost amphoteric reaction seems to corroborate Unterberger's theory. However, it must be admitted that objections such as accidental limited number, and slight differences in the percentages cannot be entirely disregarded.

Congo Red as Hemostatic.—Following a discussion of the experimental foundations of the hemostatic action of Congo red, Wedekind et al. give case reports that illustrate its efficacy in various forms of acute hemorrhages. Congo red was employed in fifty cases, namely, in hemorrhages during pulmonary tuberculosis and in bronchiectatic hemorrhages, also in menorrhagia in excessive bleeding after the extraction of teeth and in various other hemorrhages. From 5 to 10 cc. of a 1 per cent sterile aqueous solution of Congo red was administered intravenously. Secondary effects were never observed even when the injection was repeated. It was found that the injection of the Congo red solution effected an increase in the number of monocytes, which indicates a better functioning of the reticulo endothelial system. The number of blood plates and the fibrinogen content were increased and the coagulation time was reduced. Congo red was especially effective in patients with abnormalities in the composition of the blood in these instances it was superior to other hemostatics. However, in patients with a normal blood picture the result was not always satisfactory.

Chronic Myeloid Leukemia and Pregnancy—Ridder states that a review of the literature convinced him that the beginning of a pregnancy and the maturing of a healthy child is extremely rare during myeloid leukemia. He then reports the clinical history of a woman, aged 34, who complained of palpitation of the heart, of steadily increasing weakness and of pain on the left side of the abdomen. Examination revealed a large tumor of the spleen and the characteristic blood picture of myeloid leukemia. Roentgen therapy was instituted and under its influence the splenic tumor decreased and the patient's general condition improved likewise. Several months later, however, she asked medical advice, because her abdomen was again becoming larger. It was now discovered that she was pregnant. Several months later she gave birth to a full term, healthy, male child. After confinement the woman's condition became steadily worse, and two and one-half months later she died. The child developed normally, and an examination of the blood did not reveal abnormalities. The author points out that as far as can now be seen the frequent roentgen treatments have had no detrimental influence on the child.

Surgical Treatment of Ascites—Franke criticizes Lepelne's pessimistic point of view in regard to the surgical treatment of ascites. Because Lepelne's unfavorable criticism might prevent many general practitioners from seeing surgical aid for a patient with ascites, the author stresses the therapeutic value of surgical treatment. He discusses the various operative methods, namely Talm's operation and its modifications, permanent subcutaneous drainage, extirpation of the spleen as recommended by Mayo, and especially Ruotte's operation. He considers Ruotte's operation as the method of choice.

Phrenic Exeresis in Surgical Treatment of Pulmonary Tuberculosis—Naegeli and Schulte Tigges first review a former article in which they reported their observations on 100 patients who had undergone phrenic exeresis. They had found that, in 48 per cent of the patients with cavern formation, exeresis was followed by a disappearance of tubercle bacilli from the sputum. The most favorable results had been obtained in patients with secondary, round caverns, with a tendency for shrinking and in whom there were no adhesions and infiltrations in the surroundings of the cavern. Exeresis was most effective in the absence of pleuritic adhesions. Because some authorities had asserted that the permanent results of phrenic exeresis are not favorable, the authors subjected fifty-five patients who from two to four years previously had undergone phrenic exeresis to after examinations. Seventeen of the patients were free from bacilli and were able to follow their occupation. In twenty-four patients, who had had large caverns with infiltrations in their surroundings, the results were likewise favorable in that the caverns were smaller and the patients were able to do light work. However, the sputum still contained bacilli. The other fourteen cases showed no improvement but rather exacerbations. The authors come to the conclusion that the selection of patients who are subjected to phrenic exeresis should be made with great care. The comparatively simple technique of this method should not be a temptation to perform it without carefully evaluating its advisability.

Therapy of Lupus Vulgaris—Gerson Diet.—Volk first discusses the main features of Gerson's diet. It is based on the observation that a diet which effects acidity promotes the healing of infectious processes whereas a more basic diet retards the healing. The main characteristics of the diet are (1) deficiency in the sodium chloride content, (2) large quantities of rich vegetables and (3) changes in the proportions of proteins, fats

and carbohydrates. Compared with Voit's formula, which prescribes for a healthy worker 118 Gm of protein, 56 Gm of fat and 500 Gm of carbohydrates, the diet for tuberculous patients prescribes about 90 Gm of protein, 162 Gm of fat and only 222 Gm of carbohydrates. This shows a considerable increase in the quantity of fat, whereas the carbohydrates are reduced to less than half. It has been proved in animal experiments that, if the food contains excessive quantities of carbohydrates, the susceptibility to tuberculosis is heightened whereas a diet with large amounts of fats reduces the susceptibility to tuberculous infection. The author further stresses the great significance of the vitamins. In discussing the therapeutic value of the dietary treatment he states that it gives the best results in tuberculosis of bones and of joints and particularly in lupus vulgaris. Tuberculosis of the mucous membranes was also favorably influenced. In regard to pulmonary tuberculosis the author states that his observations coincide with those reported by Sauerbruch, namely, that many patients, who were in a hopeless condition improved to such an extent that they could be treated surgically. In the conclusion it is emphasized that, although the Gerson dietary treatment cannot be considered a panacea for all cases of tuberculosis, it is nevertheless a valuable therapeutic aid.

Filtrable Elements of Tuberculosis Virus—Prebacillary Granulemia.—In experiments on guinea-pigs, Calmette and Valtis demonstrated that subcutaneous or intraperitoneal injections of filtrates containing the ultravirus of tuberculosis, regardless of whether they were obtained from young cultures or from tuberculous organs, blood urine, milk exudates, pus, sputa or sputum containing tubercle bacilli, frequently caused slight enlargement of the lymph nodes without the formation of nodules. In the enlarged lymph nodes a careful search from three to eight weeks after the injection revealed typical tubercle bacilli and in addition acid fast granules. About the acid-fast granules were numerous extremely fine, barely visible dustlike granules some of which were spherical and some rod shaped. These granules were not acid fast. In many of the animals that died a few days or weeks following the injection of the filtrate postmortem examination did not reveal macroscopic changes. A careful microscopic examination of the slightly enlarged lymph nodes however usually revealed a few bacilli. Occasionally the spleen was slightly enlarged and the lungs showed small localized areas of hepatization. When the slightly enlarged lymph nodes were ground up and injected into other guinea-pigs enlargement of their lymph nodes was produced and if serial passages were made in this manner there developed after six to eight passages typical tuberculous changes with nodules undergoing caseous degeneration. Inoculations made from the nodules produced typical tuberculosis. It was also demonstrated that the invisible and virulent elements in the filtrates when injected intraperitoneally in pregnant guinea pigs caused pathologic changes in the fetuses. Young animals injected in this manner did not develop the characteristic changes in the organs noted following the injection of guinea pigs with tubercle bacilli but seemed to have a severe intoxication. Some groups of lymph nodes were greatly swollen and in them were typical acid fast bacilli. By means of serial inoculations of guinea pigs with the bacilli their characteristics could be made to approach the characteristics of typical tubercle bacilli until finally they could not be differentiated from tubercle bacilli cultivated from tuberculous organs. To substantiate this experimental observation clinically the authors examined post mortem twenty-six infants and children of tuberculous mothers. The microscopic examination showed in 89 per cent of the cases that

a transplacental infection with filtrable elements had occurred. It was noted that if this infection occurs in from the third to the sixth month of pregnancy the child frequently dies during intra uterine life or during the first weeks after birth. If it occurs in a later period of pregnancy the infection is usually non-virulent and may disappear completely, it rarely causes tuberculous changes and may even produce a transient resistance to virulent infections. These observations show that the child of a tuberculous mother frequently contains the virus of tuberculosis at birth and that from the virus true tubercle bacilli may develop. Even when they do not the virus itself produces an intoxication that may terminate fatally during the first few weeks of life. This explains why the new born infants of tuberculous mothers die so frequently and why it is impossible to demonstrate the slightest change in their organs. Those however, who are infected with the ultravirus shortly before birth and survive the infection contain a few bacilli of low virulence or benign tuberculous changes which give them a resistance to later infections. Emphasis is laid on the fact that the observations mentioned necessitate a revision of the views held until now with regard to the mode of origin of tuberculous infection. The disease called tuberculosis and characterized by the presence of inoculable giant cells containing bacilli and of tubercles in various organs is only the chronic form or the end stage of an infection caused by an ultravirus whose elements are at first invisible but gradually become nonacid fast dustlike bodies and later develop into acid fast granules and finally into tubercle bacilli. A large number of serous effusions in the pleural pericardial and peritoneal cavities and in the meninges and joints appear to be caused by the ultravirus exclusively, as do also various skin diseases (erythema nodosum, sarcoid papulonecrotic tuberculid and so on), various septicemias (typhobacillosis) and granulomas in which it is extremely difficult to find acid-fast tubercle bacilli. The recommendation is made that all these pathologic conditions in which the ultravirus of tuberculosis seems to be the main cause and in most of which the prognosis is good be differentiated from true bacillosis and be designated as "prebacillary granuloma."

Chorio-Epithelioma with Rare Clinical Symptoms—

According to von Rausz, the recognition of a chorio epithelioma is, in most instances not difficult especially when a hydatid mole pregnancy has preceded. In the case reported, however, the clinical symptoms differed from those that are usually observed. The author describes the clinical history of the case. He thinks there can be no doubt that the chorio epithelioma was the sequela of the hydatid mole of five years previous. The amenorrhea was probably the result of the repeated curettage by which the entire mucous membrane had been destroyed. Examination of the scrapings removed during curettage gave no indications for an existing chorio-epithelioma. The chorio epithelioma had originated in an intramural focus, and this is why fragments of the chorio epithelioma were not found in the material removed by curettage, and this also explains why hemorrhages, which are usually the main characteristic of chorio epithelioma were absent. Because cases without hemorrhage are extremely rare, the disorder was not recognized as chorio epithelioma. The operation revealed that the destructive growth in the uterine wall had spread to the bladder and to the parietal peritoneum. The patient died thirty-one days after the operation. The hemorrhages, which had not been external, had been internal between the tissues and into the abdominal cavity in accordance with the direction of the growth. In the conclusion, the author stresses the value of the Zondek-Aschheim reaction. He thinks that if this test had been made following the hydatid mole pregnancy, the chorio epithelioma would have been detected earlier.

Fasting Cures in Hyperemesis Gravidarum—Offergeld asserts that hyperemesis gravidarum is mainly due to metabolic disturbances and to an increased irritability of the sympathetic nervous system. Accordingly, he advises hormone therapy. He recommends hormones of the ovaries and of corpus luteum. Whether thyroidal hormone and also small amounts of the suprarenal hormone are advisable depends on the individual case and occasionally extracts of other organs might be helpful. Because fasting often counteracts vomiting, it might also prove helpful in hyperemesis gravidarum. A prolonged fasting cure might be injurious to a pregnant organism, but a shorter fast of one or two days can be safely employed. The author found it helpful in addition to the hormonal substitution therapy, however, he gave about 1.5 liters of fluids. If during this time favorable results are not obtained it is useless to prolong the fasting cure. Besides the complete fast the author recommends a changed diet. A diet rich in proteins should be abandoned in favor of a fruit and vegetable diet. The author thinks that hyperemesis could be avoided in many instances if, during the beginning of pregnancy, a diet too rich in proteins and fats is avoided, and instead a more vegetarian diet is adopted.

NEPHRITIS AND ITS RELATION TO CARDIOVASCULAR DISEASE*

WILLIAM OPHULS, M.D.

SAN FRANCISCO

For the purpose of statistical investigation,¹ a series of 212 cases of diffuse nephritis have been segregated into the following groups

1 *Acute nephritis*, 21 cases. This group includes acute interstitial and acute glomerulonephritis with the exclusion of all purely degenerative lesions.

2 *Subacute nephritis*, 41 cases. This group includes all cases of subacute and subchronic glomerulonephritis.

3 *Amyloid nephritis*, 49 cases. This group includes all of the cases that would fall under the heading of "complicated nephrosis" of Fahr or of degenerative Bright's disease or Addison.

4 *Chronic nephritis*, 101 cases. This group represents largely what by others has been designated as malignant nephrosclerosis" or the "combination form of arteriosclerotic nephritis."

In my opinion the cases of "benign nephrosclerosis" have a closer relation to cardiovascular disease than to nephritis because the lesions in the kidneys are relatively insignificant and, as will be shown later, are probably of no great functional importance.

ACUTE NEPHRITIS

Of the twenty-one cases of acute nephritis six showed the histologic picture of acute interstitial nephritis and fifteen that of acute glomerulonephritis.

In acute interstitial nephritis the kidneys were more or less swollen and often distinctly opaque and grayish. The hemorrhagic spots that are so characteristic of glomerulonephritis were missing. The interstitial tissue was irregularly infiltrated with lymphocytes and plasma cells. The epithelium may have been slightly damaged. The urinary changes usually were slight and the cases did not present the usual clinical picture of acute nephritis.

In acute glomerulonephritis the kidneys were often considerably swollen and intensely congested. The renal cortex was full of punctiform hemorrhages which could be clearly seen after the removal of the fibrous capsule (fig 1). The histologic investigation revealed primarily a congestion and leukocytic infiltration of the glomeruli which was followed by the discharge of a hemorrhagic exudate into the capsular spaces and into the corresponding numerous tubules. Some of the

loops of the glomeruli may be filled with hyaline thrombi and undergo necrosis. The bloody fluid that escapes from the damaged glomeruli may coagulate in the capsular spaces and plug them with a meshwork of fibrin enclosing red cells and polymorphonuclear leukocytes. Similar coagula may form in the tubules. This often leads to the formation of leukocytic and blood casts. The tubules were wide and the epithelial cells that lined them often showed various forms of degeneration. The capillaries surrounding the tubules were greatly congested. The interstitial tissue was edematous and filled with neutrophilic leukocytes and lymphocytes. The urinary changes were marked and consisted in the presence of much albumin, many red cells, leukocytes, blood casts and other types of casts, also of free epithelial cells. The frankly bloody appearance of the urine was characteristic. If many glomerular capsules were plugged, the amount of urine was sometimes reduced to complete anuria. Apart from the renal changes the patients often developed edema of the face which sometimes spread to the rest of the body. It is probable that this "renal" edema was due to capillary injury in the edematous parts due to the same toxin that produced the nephritis. A rise of systolic blood pressure may be observed even in the acute cases. One of the patients had developed an acute progressive meningitis.

The etiology was similar in the two types of acute nephritis. Figure 2 shows that in practically all the cases the renal lesions were due to acute septic infection with various types of pyogenic micrococci such as staphylococci (one case), pneumococci (three cases, two of lobar pneumonia and one of empyema) and streptococci in the remaining cases. One of the latter was a case of viridans endocarditis and one a case of scarlet fever. The remainder were infections with hemolytic streptococci in such diseases as tonsillitis, Ludwig's angina, otitis media, puerperal fever, pelvic abscess, erysipelas, cellulitis, infected compound fracture and septic dermatitis.²

In spite of the great frequency of severe streptococcal infections acute nephritis is a relatively rare disease. This would seem to indicate that special conditions must arise in order to produce it.

In the majority of the cases the death of the patient was to a great extent due to the septic infection. In a few cases only did the nephritis contribute materially to the fatal issue.

From the common experience in scarlet fever it is evident that a complete recovery from these acute lesions is possible. The abnormal contents of the capsular spaces and of the numerous tubules are swept out by a flood of urine. The glomeruli recover so far as they

have not actually been destroyed, the inflammation subsides in the rest of the tissues, and the lost epithelial cells are regenerated. Reexamination after many years has shown that this recovery is often perfect and lasting.

A favorable outcome, however, is often prevented by persistence of the septic infection and by the severity of the renal lesions.

Fig. 1—Kidneys in acute glomerulonephritis

SUBACUTE NEPHRITIS

The forty-one cases of subacute diffuse nephritis represent all stages of subacute and subchronic glomerulonephritis. As shown in figure 3, the etiology was similar to that found in cases of acute nephritis, namely, streptococcal endocarditis in fifteen cases, streptococcal tonsillitis in seven cases, diplostreptococcal septicemia in two cases, severe tooth abscesses in two cases, and septic leg ulcers in two cases. An old syphilitic infection may possibly have been the cause in two cases while no definite etiology could be established in six cases.

The group is a homogeneous one and presents characteristic gross and anatomic lesions. The majority of the kidneys were moderately enlarged. The cortex was wide and opaque, irregularly congested with scattered small hemorrhagic spots (fig. 4). Only a few late cases showed kidneys of normal size or even a slight reduction below the normal (fig. 5).

The glomeruli exhibited various stages of glomerulitis from the early hemorrhagic lesions to crescent formation and invasion of the vascular tufts by connective tissue ending in complete fibrosis. All the different stages could often be seen in the same specimen, suggesting that the lesions occur in successive crops. A varying number of tubules were filled with blood and casts. The amount of epithelial degeneration varied from a slight parenchymatous change to severe fatty degeneration and necrosis. The capillaries between the tubules were greatly congested and the interstitial tissue was heavily infiltrated with round cells, among which in the early stages neutrophilic and often many eosinophilic leukocytes were frequently encountered. As the process continued, a progressive proliferation of the connective tissue had taken place with collapse of groups of tubules. Local arterial lesions were sometimes absent even in the last stages of the process, or they had developed early and in time had become well marked. In the arterioles they consisted in a deposit in their walls of hyaline material which is later followed by

fibrosis, while in the larger arterial branches the picture was one of progressive endarteritis. In a certain proportion of relatively late cases the local arterial changes were accompanied by moderate arteriosclerosis in other parts of the body.

A study of the relation of the arterial changes to the blood pressure is interesting. As shown in figure 3, in twenty-one (about 50 per cent) of the forty-one cases of subacute diffuse nephritis the arteries were perfectly normal in the kidneys and elsewhere in the body. In spite of this a definite elevation of blood pressure had been observed in eight (about 40 per cent) of this group and a hypertrophy of the left ventricle had already developed in seven of these. In ten cases the arteries in the kidneys were diseased, while those elsewhere were normal, six (about 60 per cent of this group) of these patients had high blood pressure and hypertrophy of the left ventricle. In the remaining ten cases arterial disease was present in the kidneys and to a moderate degree elsewhere. Nine of these (90 per cent of this group) had had high blood pressure, and eight of the nine cardiac hypertrophy. It is evident that hypertension frequently occurs in the absence of any demonstrable arterial lesions but that it is more common in cases in which they are present.

The urinary changes were usually well marked and blood could be found in the urine, if not always, at least from time to time.

Edema had been present in more than half of the cases but it had been constantly absent in a certain number of them.

Fig. 2—Number of cases and etiology in acute nephritis. This and the accompanying diagrams to figure 9 inclusive indicate the actual number of cases observed under each heading.

Fig. 3—Number of cases etiology and cardiovascular lesions in subacute nephritis. In this and the accompanying diagrams the degree of arteriosclerosis is indicated by perpendicular lines interrupted by lines indicate local arteriosclerosis only, diagonal hatching indicates high blood pressure.

A progressive secondary anemia had developed in about the same proportion of cases but without reference to the presence of edema. In one case the blood picture closely resembled that of pernicious anemia.

The phenolsulphonphthalein excretion, when tested, was usually found retarded and in severe late cases almost suppressed. Correspondingly there was often a urea retention in the blood.

Albuminuric retinitis had been observed in a few cases only.

The causes of death, so far as could be ascertained, had been as follows: bacterial endocarditis in nine, septic infection in six, cardiac decompensation due to old valvular dis-

Fig 4—Swollen kidney in subacute nephritis

Fig 5—Shrunken kidney in late subacute nephritis

ease in one, acute cardiac failure in one, pulmonary embolism in one, uremia in ten, cerebral hemorrhage in three, anemia in one, bronchopneumonia in four, tuberculosis in one, and suicide in one. In other words, fifteen patients (nearly 40 per cent) had died of the underlying septic infection and fourteen (35 per cent) as a direct result of the nephritis. Among the latter group uremia was most common, next in frequency was cerebral hemorrhage. It is doubtful whether any of the patients had died as a result of a derangement of their general circulation which had been caused by the presence of the nephritis.

AMYLOID NEPHRITIS

The cause of the amyloidosis and of the incidental nephritis was evident in all forty-nine cases of amyloid nephritis. As shown in figure 6 the lesions were due to chronic tuberculosis in twenty-seven cases, to chronic syphilis in five, to leprosy in two, to chronic septic infection in nine, and to malignant tumors in two.

During the earlier stages of the process the kidneys were definitely enlarged, often to a considerable size. The cortex was wide and exceedingly opaque white or yellowish. Hemorrhagic spots were usually absent. Later, by shrinkage, the kidneys were sometimes reduced to normal size or below that. The shrinkage was either diffuse or more irregular leaving a rough surface in the latter case.

The deposition of the amyloid in the glomeruli was accompanied by a slowly progressive fibrosis which gradually caused a fibrous obliteration of many glomeruli. The epithelial lining of the convoluted tubules and of the ascending limbs of the loops of Henle showed marked granular and fatty degeneration. The tubules were full of hyaline casts. In the early stages one found a moderate perivascular round cell infiltration which eventually was followed by a slow connective tissue proliferation. In the course of time this may lead to the development of scars of a considerable size with collapse of the tubules. Local vascular changes

were present in twenty cases (40 per cent) and moderate general arteriosclerosis in five cases (10 per cent). In both groups there was one case each with cardiac hypertrophy and in addition in the first group one case of hypertension without cardiac hypertrophy.

The contrast between the two forms of subacute diffuse nephritis is striking. In amyloid nephritis there were three cases of high blood pressure among forty-nine, or 6 per cent, while in ordinary subacute nephritis there were twenty-four among forty-one, or 54 per cent. The relative rarity of arterial lesions in amyloid nephritis is also apparent. In amyloid nephritis none of the cases with normal blood vessels showed hypertension, and relatively few of those with moderate local and general arteriosclerosis.

Urinalysis always revealed marked changes in the urine, usually, however, without evidence of hemorrhage.

Edema was common but by no means constant.

Progressive anemia was not particularly frequent.

In late cases uremic symptoms had been observed occasionally and modern methods sometimes had revealed a marked decrease in functional activity.

The presence of albuminuric retinitis had not been recorded in any of these cases.

Almost all patients with amyloid nephritis had died not of the nephritis but of the chronic infections which had caused the amyloidosis, such as chronic pulmonary tuberculosis, chronic syphilis, leprosy, chronic septic infections or carcinoma. Only a few of them had died of uremia.

CHRONIC NEPHRITIS

This group of 101 cases has been carefully restudied with the object of discovering whether it is possible to subdivide it into two subgroups: one with primarily vascular and one with primarily glomerular and parenchymatous lesions. The relative proportion of the involvement naturally varies in different cases and there are a few extreme cases in which the lesions do not involve the blood vessels or in which the arterial changes are by far the most important ones, but in most of them the glomeruli, the parenchyma and the blood vessels all show characteristic alterations. Even in cases with extreme vascular lesions one can usually find evidence of healed or even still active glomerulitis. If one assumes that the same causative factors affect the glomeruli and the parenchyma as well as the blood vessels, but to a different extent in different cases, the distinction between the different forms of chronic nephritis loses much of its significance. It is certainly true that, however the lesions may have been brought about originally, the final anatomic and clinical results are similar.

On account of the insidious nature and the chronicity of the disease the etiology is much more difficult to determine than in the more active cases of subacute nephritis. It is significant, however, that the histories in

49	
* Subacute Nephritis in Amyloidosis	
tuberculosis	27
syphilis	5

chron. septic	9
tumors	2
49	

Fig 6—Number of cases of amyloidosis in amyloid nephritis

Fig 6—Number of cases of amyloidosis in amyloid nephritis

a large proportion of the cases tell of early and repeated attacks of tonsillitis and that anatomically one can often still demonstrate the presence of old septic foci in the tonsils or in other parts of the body.

The kidneys in this group were all shrunken and usually more or less distinctly granular (fig 7). Their fibrous capsules were thickened and, to a varying degree, adherent. The color of the renal tissue depended on

Fig 7—Shrunken granular kidney in chronic nephritis

the amount of degeneration in the numerous tubules and on the amount of congestion present. As a rule there were purple retracted vessels and between them were remnants of kidney tissue varying from a gray to a bright yellow, the latter indicating advanced fatty degeneration. On the cut surface the cortex was greatly reduced. The small blood vessels were usually more or less thickened. In the pyramids, bright white linear uric acid deposits were found in at least one fourth of the cases. Their presence was sometimes but not frequently accompanied by gouty deposits in the basal joints of the great toes or in other joints. As a result of the shrinkage of the renal tissue an unusually large amount of fatty tissue often filled in the spaces around the renal pelvis. The microscopic picture was dominated by an extensive, usually patchy, fibrosis on the one hand and the presence of islands of relatively intact renal tissue on the other. These remnants of functioning tissue often showed a marked compensatory hypertrophy. No doubt it is their existence which permits of the long continuance of the life of the patients. In the cicatrized portions the glomeruli were fibrosed, the tubules collapsed or sometimes cystic, the interstitial connective tissues greatly thickened. Degenerative changes were frequently observed in the remaining tubules and in the diseased glomeruli.

As shown in figure 8, the arteries were almost invariably diseased, not only in the kidneys but also in other parts of the body. In only three cases (about 3 per cent) were no serious lesions found in the blood vessels locally or generally in spite of the presence of severe lesions in the renal tissue. None of these patients had had high blood pressure nor had they developed cardiac hypertrophy. In twenty cases (24 per cent) the arterial lesions were of a moderate degree and limited to the kidneys. In three of these (about one sixth of this group) hypertrophy of the heart had not developed. A moderate degree of arteriosclerosis had been present in the kidneys and elsewhere in thirty-six patients (about 40 per cent). Hypertrophy of the heart was found in all of these as also in the group of twenty-four patients (about 30 per cent) with severe local and general arteriosclerosis. Among all cases of

chronic nephritis there were only six or approximately 7 per cent, without cardiac hypertrophy.

Marked changes in the chemical composition and in the morphology of the sediment of the urine were observed in many cases. Frequently in the late stages polyuria and a fixed low specific gravity had been noted. When tested, the phenolsulphonphthalein excretion was found to be greatly delayed and, toward the end, almost completely stopped.

Edema had been observed in more than half of the cases, but it had been constantly absent in a considerable number of them.

Secondary anemia had been present in about one half of the cases. In a considerable proportion of cases, however, the blood had remained perfectly normal to the time of death.

Toward the end, marked retention of urea had occurred frequently and about one half of the patients had died in uremia. In these cases ulcerative and gangrenous stomatitis and enteritis, also acute pericarditis, were frequent terminal complications. The next most important cause of death was cardiac decompensation, which had developed in one third of the cases. Cerebral softening or cerebral hemorrhage had occurred in relatively few of them.

Albuminuric retinitis had been discovered in about one fifth of all cases of chronic nephritis.

There remains an interesting group of eighteen cases in which the renal lesions were less extensive than they are in the ordinary cases of chronic nephritis but more pronounced than they usually are in uncomplicated cases of general arteriosclerosis. They form a connecting link between chronic nephritis and cardiovascular disease. They are diagrammatically represented at the top of figure 8. It is shown there that two of them were free from all vascular lesions, eight had moderate local and general arteriosclerosis, and eight more had severe local and general vascular lesions. Hypertrophy of the heart was not present in the two cases without vascular lesions, while hypertrophy of the heart had developed in three of the eight cases with moderate general arteriosclerosis and in five of the eight cases with marked general arteriosclerosis. The large majority of the patients of this intermediate group had died of diseases not connected with the renal lesions such as septicemia, mitral stenosis, diabetes, pulmonary tuberculosis and cirrhosis. The cause of death was doubtful in three cases. Of the most advanced cases, only three patients died in uremia and one of cerebral hemorrhage. With many of the patients it was definitely known that during life they had never had any nephritic symptoms. Gouty deposits were found in the kidneys in three patients and retinitis had been discovered in two.

Fig 8—Number of cases etiology and cardiovascular lesions in chronic nephritis

CARDIOVASCULAR DISEASE

While the total number of cases of nephritis was only 212 or 7 per cent of all the cases of the series,

there were 917 cases of general arteriosclerosis without serious renal involvement, representing 30 per cent of all the cases. In two thirds of these 917 cases the arterial lesions were of a moderate degree, while in one third of the cases they were of a severe nature.

Hypertrophy of the heart was present in about one third of all the cases of general arteriosclerosis. It was much more common in the severe cases, in which it was observed in two thirds of the cases, while it had occurred in less than one seventh of the cases in which the arteries were only moderately affected. The condition is shown graphically in figure 9, in which the 212 cases of nephritis with their relation to arteriosclerosis and high blood pressure are charted on the left and the 917 cases of uncomplicated general arteriosclerosis on the right. It shows that quantitatively cardiovascular disease is by far the more important problem.

An attempt has been made to separate the cases with slight focal lesions in the kidneys which are, of course, rarely absent, from those with more pronounced but still moderate focal changes in order to determine whether the degree of renal involvement had any relation to the height of the blood pressure. The result was as follows. In severe arteriosclerosis with slight renal lesions hypertrophy of the heart had developed in about 62 per cent of the cases, while in severe arteriosclerosis with more marked renal lesions it had been observed in 65 per cent of the cases. The difference is practically negligible.

In moderate general arteriosclerosis the actual number of cases of high blood pressure in cases with slight renal lesions exceeds that of those in cases with moderate renal lesions. Relatively there is probably no significant difference between the two groups because naturally the number of cases with slight renal lesions greatly exceeds those with more marked renal changes.

It may be stated, therefore, that the extent of the minor renal lesions in general arteriosclerosis is of no importance so far as the development of high blood pressure and cardiac hypertrophy is concerned.

On the other hand, the great frequency of high blood pressure in subacute and chronic nephritis even in cases with slight or moderate vascular lesions, is clearly shown on the left side of the diagram. For example, in chronic nephritis without any or with only local arterial changes, about three fourths showed hypertension. Hypertrophy of the heart was present in all cases of subacute and chronic nephritis with moderate or severe general arteriosclerosis. In subacute nephritis quite a few cases with normal arteries locally and generally had high blood pressure and the proportion was greater when there were moderate arterial changes locally or generally. It is evident therefore that hypertrophy of the heart occurs much more frequently when the arterial disease is associated with serious renal lesions.

The great majority of patients with cardiovascular disease unless killed by intercurrent disease died of decompensation or more rarely of cerebral softening or hemorrhage.

AGE INCIDENCE IN NEPHRITIS AND GENERAL ARTERIOSCLEROSIS

The striking difference in age incidence between nephritis and cardiovascular disease is brought out clearly in figure 10 in which the age incidence of nephritis is shown on the left and the age incidence of arteriosclerosis on the right.

In the construction of this diagram, all cases of subacute and chronic nephritis were segregated into the following groups:

1 Nephritis with normal arteries without cardiac hypertrophy (a large part of this group were cases of amyloid nephritis)

2 Nephritis with normal arteries with cardiac hypertrophy

3 Nephritis with moderate arterial lesions without cardiac hypertrophy

4 Nephritis with moderate arterial lesions with cardiac hypertrophy

5 Nephritis with severe arterial lesions with cardiac hypertrophy (There were no cases of nephritis with severe arterial lesions without cardiac hypertrophy.)

For each group, the relative incidence in each age group was determined and plotted. The result is shown on the left side of figure 10. The number of cases of nephritis at no age exceeded 10 per cent of all the cases in the age groups. There were few cases in the first decade altogether, three without vascular lesions. Two of these showed cardiac hypertrophy. The maximum 10 per cent was reached in the second decade,

Fig 9—The combined picture all cases of nephritis on the left and all cases of uncomplicated cardiovascular disease on the right.

during which seven cases had been observed. None of these had arterial lesions and two had developed cardiac hypertrophy. During the third, fourth and fifth decades the actual number of cases is much greater but not their relative proportion to the total number of cases in each age group. The cases in the later years show more marked arterial lesions and a greater incidence of cardiac hypertrophy. From the age of 50 on the patients with nephritis become less frequent. Only three miscellaneous cases were found in the group over 70 years of age. This diminution in the number of patients with nephritis later in life is evidently due to the relatively early death of the patients.

The age incidence of general arteriosclerosis as shown in figure 10 is of a very different character. The first few cases of slight general arterial disease were observed in the third decade. Between 30 and 40 there was a moderate increase to 6 per cent and at this age already a few cases of severe general arteriosclerosis were encountered. In the group between 40 and 50, almost one fourth of the patients had developed vascular lesions. The ratio of cases with severe lesions to those with more moderate ones was approximately 1 to 5. Between 50 and 60 general arterial disease was found

in nearly one half of the patients the ratio of severe cases to lighter ones remaining about the same, namely, 1 to 5. Nearly three fourths of the patients showed generalized vascular lesions between 50 and 60 and the ratio of the severe cases to those with moderate changes increased to somewhat less than 1 to 2. Among the patients over 70 years of age, nearly nine tenths exhibited vascular lesions and the ratio of severe to moderate cases changed to somewhat more than 1 to 2. There was therefore a rapid increase of generalized arteriosclerosis with advancing age and the arterial lesions tended to become progressively more marked.

The frequency of cardiac hypertrophy in uncomplicated cases of general arteriosclerosis, all cases included, rose from about 25 per cent at ages between 20 and 60 to 40 per cent in patients over 60 years of age. No explanation has been found for this sudden rise from 25 per cent to 40 per cent after 60 years of

etiology of amyloid nephritis is given by the diseases that produce amyloidosis, such as chronic sepsis, tuberculosis, syphilis and malignant tumors. The indications are that in the causation of chronic nephritis also chronic septic infection of a focal character is of importance.

5 The amount of arterial involvement in otherwise similar cases of nephritis varies greatly from nothing at all to very severe lesions locally and generally.

6 In nephritis high blood pressure often develops without the presence of any arterial lesions in the kidneys or elsewhere and it is almost constant when there are arterial changes, even when they are present only locally. There are a few cases of extreme chronic nephritis without vascular lesions which do not develop any elevation of blood pressure.

7 Edema and secondary anemia are frequent complications of nephritis but their occurrence is quite inconsistent and bears no direct relation to the char-

acter or the extent of renal lesions. Edema and anemia are probably caused by the same factors that underlie the development of the nephritis. The noxious agents evidently vary greatly in their effect on the blood and the capillary blood vessels.

8 In acute nephritis the deaths are usually due to the infection that caused the nephritis. This is also true of amyloid nephritis. In subacute nephritis a considerable proportion of the patients die of the infectious process that causes the nephritis. About the same number succumb to conditions con-

nected with their renal disease. Chronic nephritis is usually the direct cause of death and most of these patients die of renal insufficiency.

9 Connecting chronic nephritis and uncomplicated cardiovascular disease, there is a small group of cases that exhibit serious but limited renal lesions. High blood pressure is not so constant in them as in typical cases of chronic nephritis. Only a few of these cases finally develop signs of renal insufficiency.

10 Numerically, general arteriosclerosis is a much bigger problem than nephritis but only one third of the cases develop disturbances in the general circulation. High blood pressure and cardiac hypertrophy occur more frequently when the lesions in the blood vessels are well marked but it may develop in individuals with nearly normal blood vessels.

11 In general arteriosclerosis, moderate focal renal lesions have no effect on the blood pressure.

12 The usual cause of death in uncomplicated cardiovascular disease is cardiac decompensation.

Fig. 10—Differences in age distribution in nephritis and general arteriosclerosis on a percentage basis

age. In moderate general arteriosclerosis the incidence of cardiac hypertrophy varied between 15 and 20 per cent without reference to advancing age. In marked general arteriosclerosis the incidence of cardiac hypertrophy is much higher, varying between 50 and 70 per cent without any definite relation to advancing age. The highest figure, 70 per cent, was found in the age group 60 to 70.

CONCLUSIONS

1 Nephritis and cardiovascular disease are so closely connected with each other that a separate consideration fails to afford a complete view of the problem.

2 The term nephritis should be reserved for cases in which there are serious diffuse inflammatory lesions in the kidneys.

3 The general run of cases of nephritis can be conveniently classified as (1) acute, (2) subacute, (3) amyloid and (4) chronic nephritis.

4 Acute and subacute nephritis are almost invariably due to septic, particularly streptococcal, infection. The

13 Nephritis often develops early. Its incidence in the different age groups remains about the same and never exceeds 10 per cent of all cases in any age group.

14 General arteriosclerosis develops late and increases rapidly and constantly in incidence, reaching nearly 90 per cent in persons over 70. The relative frequency of high blood pressure in general arteriosclerosis at different ages is about the same except late in life, when it seems to be considerably higher.

INTRATHORACIC GOITER *

GEORGE M. CURTIS, M.D.
CHICAGO

Still too frequently patients are seen with intrathoracic goiter that has escaped recognition even in competent hands. This is due to the fact that a meager symptomatology has not seemed to warrant taking a roentgenogram of the trachea. Since the treatment of intrathoracic goiter is essentially surgical, it is of advantage to practice this early, before the goiter has become too large, adherent or even malignant. As a consequence, I am again calling attention to this disease by presenting a review of ninety-one cases and of the literature, particularly of those papers which have appeared during the past fifteen years. Sixty-six of the cases are from the Surgical Clinic of the University of Berne,¹ the remainder are from the Billings Hospital.

That goiter may extend deep into the thoracic cavity was observed as early as 1749 by the Bernese anatomist Albrecht von Haller,² in the dissecting rooms at Goettingen. One of the first clinical cases was reported by Dubourg³ in 1826. Death occurred suddenly from strangulation and at necropsy he found what appeared to be a right partial intrathoracic goiter. Adelman,⁴ in 1828, recognized a malignant intrathoracic goiter in a man of 40. This occurred on the left side, infiltrated the surrounding muscles, and was adherent to the cervical and upper thoracic viscera. In 1851, Bonnet⁵ called attention to those forms which compress and deviate the trachea. Mahrd,⁶ in one of the first monographs (1879), collected reports of eleven cases, all from the French literature. Wuhrmann's summary of the previous reports (1896) marks the end of the early periods, since in 1895 Roentgen announced the discovery of the "shadows," which were soon applied (1899) to the recognition of intrathoracic goiter⁷ and which have since become so important in its diagnosis.⁸ Wuhrmann collected and analyzed reports of ninety-one cases, sixteen of which were malignant. His mono-

graph is still a mine of information for students of this disease, as it lays the foundation for subsequent studies. The principal addition since its publication has been the roentgenologic evidence.

The simple classification of intrathoracic goiter introduced by Wuhrmann is somewhat confused at present for two principal reasons: first, the subsequent introduction of numerous descriptive terms, and, second, the varying opinion regarding the designation of the partial forms. For this reason, statistical studies are difficult and may be unclear.¹⁰ The thoracic cavity is bounded above by a plane, convex superiorly, extending from the upper manubrium across the top of the first thoracic vertebra and laterally along the first ribs. At rest, ordinary goiters frequently extend through this opening into the thoracic cavity. On swallowing, straining or otherwise increasing the intrathoracic pressure, the lower poles of these goiters are drawn above this plane, or pushed above by the action of the pleura. These are the deep goiters (*struma profunda*). They are readily recognized since, when the patient swallows or strains, then lower poles rise and may readily be palpated above the manubrium or behind the clavicles. Figure 1 presents an excellent example of this type since the lower pole of one lobe was formed by a calcified goitrous nodule, A, whose movements could be followed, both by palpation and fluoroscopically. The important criterion is that this type moves out of the thorax on swallowing or straining. It is not a true intrathoracic form.

The total or complete intrathoracic forms may occur with or without a cervical goiter. If they occur without a cervical goiter, or simultaneously with the absence of a lobe or the isthmus¹¹ they are readily classified since they lie entirely below this superior plane of the thorax. They may occur as distinct lobes attached to a cervical goiter by a narrowed strand of goitrous tissue. They are very rare as goiters developing independently in aberrant thyroid tissue.¹² To some this is the only true intrathoracic goiter.

The partial forms seem to be the most confusing since they are intermediate between the deep and the total intrathoracic goiter. They are always accompanied by a cervical goiter, a greater or lesser part of which extends into the thoracic cavity and remains there even on swallowing or straining. Those that grow toward the median line and anteriorly are commonly called retrosternal, substernal, median or mediastinal. Those more lateral in position are designated

Fig. 1—Deep goiter showing the intrathoracic position of the calcified lower pole A with the patient at rest.¹

lateral, suprapleural and retroclavicular or, more frequently, subclavicular. It is clear, however, on examination of the skeleton that a low goiter may be subclavicular without being intrathoracic. Some extend behind the trachea or esophagus and become the retrovisceral forms.¹³ They have been further subdivided

Fig. 2—Partial intrathoracic goiter with venous obstruction and medusa head.¹

as lying ahead of the large vessels, prevascular types, or behind the large vessels, retrovascular types.¹³ Regarding the superior plane of the thorax as the boundary line and the effects of swallowing or straining on its movement, it is readily possible to determine the type of the goiter in question both at the physical and the fluoroscopic examination, and at operation. The cases considered here consist of eighty-six partial and five total intrathoracic goiters.

The reported incidence of intrathoracic goiter presents great variations, from 6 to 32 per cent,¹⁴ for two principal reasons: first, the irregularities of classification, and, second, the relative prevalence of endemic goiter. Higgins' collection of the statistics reveals the variation introduced by failing to differentiate deep goiter from the partial intrathoracic forms. It is apparent that intrathoracic goiter is more frequent in regions where endemic goiter is prevalent.¹⁵ This is evident in the present series. Twenty-four per cent of 270 successive thyroidectomies in the Berne clinic

revealed total or partial intrathoracic goiter, while but 15 per cent of similar operations at the Billings Hospital are so regarded. Berne is nearly in the center of a region of severe endemic goiter. The incidence of intrathoracic goiter in the Middle West is evidently between 10 and 15 per cent,¹⁶ with between 1 and 2 per cent of total intrathoracic forms.

Intrathoracic goiter may occur at any age. Congenital cases are rare.¹⁷ It is essentially a disease that is recognized in middle life. Higgins finds it commonest in the fifth and sixth decades. Pemberton gives the average age as 46.11 years. It is frequently stated that it usually occurs after the age of 40. However, the average age of the sixty-six Berne patients was but 34 years, in the Chicago cases it was 49 years. Our youngest patient was 13 years of age, the oldest 70. It is more common in women. This is reported as in essentially similar proportion as nodular goiter is more frequent in females.¹⁸ Our cases, however, show an even greater preponderance. Jackson¹⁹ reports twenty-three of twenty-five total forms in women.

Intrathoracic goiter is nearly always nodular and frequently cystic in character.²⁰ Only 3 of Higgins' 100 total cases were diffuse goiters. Jackson states that 95 per cent are nodular. Only two of our ninety-one cases were diffuse colloid forms, the remainder were nodular (struma nodosa) or nodular and cystic. Intrathoracic goiter is thus of the endemic type, which accounts for its greater frequency in regions of severe endemism. Developing from the lower poles or isthmus, the nodular or cystic projection enters the superior strait of the thorax. Further intrathoracic development is facilitated by three principal factors: breathing, particularly deep inspiration, muscular action,

Fig. 3—Total intrathoracic goiter, malignant with pulmonary metastases, pressure on azygos vein and right hydrothorax.

ity in flexing and rotating the head,²¹ and the nonresistance of the more pliant structures of the superior

mediastinum. Gravity is mentioned by some, as well as the frequent movement of the thyroid in swallowing. Thyroptosis, more common in patients with emphysema (von Eiselsberg), predisposes to an intrathoracic extension.

As the nodular mass develops, its cervical attachment may become attenuated, and the intrathoracic extension thus becomes more freely movable (*struma mobilis*).

Fig 4—Total intrathoracic goiter, oblique view after thoracentesis showing the large cystic mass.¹

These "diving goiters" (*tauchkropf*) readily disappear into the thorax on deep inspiration, reappearing suddenly in the neck on straining. This may be observed fluoroscopically.²² Certain cervical forms later descend, enlarge and eventually become caught under the nonyielding bony ring of the superior thoracic aperture (*Wanderkropf* Wolfier). Acute incarceration of this type has caused fatal suffocation.²³ Diving or wandering forms may remain thus imprisoned for a long time and then suddenly reappear in the neck following an acute increase in the intrathoracic pressure or a sudden extension of the head (*springkropf*). Such an acute dislocation has led to severe hemorrhage.²⁴ Unattached intrathoracic goiters are very rare.² An intrathoracic extension may be overlooked during a thyroidectomy.²⁵

Intrathoracic goiter occurs more frequently on the left side.²⁶ Wulffmann's early summary, however, showed a more even distribution, 37 per cent originating on the right side, 33 per cent from the isthmus and but 30 per cent from the left side. The explanation is that the majority of those originating in the isthmus are deviated to the left by the anterior lying innominate artery. This is particularly well shown in one of Wegelin's¹² illustrations (fig 104). Bilateral forms occur²⁷

Genuine exophthalmic goiter most rarely becomes intrathoracic, however, it often forms a deep goiter. This demonstrates the significance of the nodules in the pathogenesis of the intrathoracic forms.

The symptoms of intrathoracic goiter are principally those of mechanical pressure on the mediastinal structures. Thyrotoxicosis is not so common in endemic regions. Only 3 per cent of the Berne cases presented toxic symptoms. Dyspnea is the most common single symptom, although it may be slight or even absent in masked total forms.²¹ Intermittent attacks of suffocation or of strangling occur, particularly with certain positions of the head.²² Bronchostenosis with its sequelae has been described.⁹ Intrathoracic goiter is a considerable complication to major surgery.²³ Dysphagia is not so frequent and occurs particularly with the retrovisceral forms, or with those on the left side.²⁴ By pressure on the esophagus, the goiter may predispose to the formation of pulsion diverticula.²⁵ Unilateral recurrent palsy more commonly left, occurs in about 15 per cent of the cases.¹⁸ Bilateral palsy may occur³⁶ (figs 3 and 4). Phrenic palsy has been reported.³⁷

The cervical veins are congested and are obviously dilated in about 15 per cent of the cases.¹⁹ A medusa head may thus occur about the base of the neck (fig 2). Marked varicosities of the axillary veins due to pressure stasis have been described,³⁸ and similarly hydrothorax may develop (fig 3). The innominate vein may even become obliterated (Phillips). Schultze¹² reported chylothorax subsequent to pressure on the opening of the thoracic duct.

One of the unsolved problems of intrathoracic goiter is its mechanical effect on the heart.³⁹ Partial tracheal stenosis causes changes in the respiratory mechanism. Obstruction to the return flow of blood through the superior cava produces changes in the cardiac circulation. Rose thought (1878) that these mechanical effects act on the heart.

As a consequence the concept of a "mechanical goiter heart" has been frequently considered. It is difficult to separate the effects of thyrotoxicosis. Many of the observations were recorded before the advent of accurate determinations of the basal metabolism. Sulzer found experimentally that not all forms of tracheal stenosis

Fig 5—Partial intrathoracic goiter, preoperative compression and deviation of the trachea.

cause cardiac dilatation.⁴¹ This is recognized clinically. The interrelationship is not clear.

The diagnosis of intrathoracic goiter is readily made by the x-rays. The clinical symptoms and signs of

importance are dyspnea, choking and strangling attacks, and laryngeal and tracheal deviation.⁴¹ Intrathoracic goiter should always be considered in the evaluation of obscure asthmatic conditions.⁴² Fluoroscopy is of great aid in the differential diagnosis of the intrathoracic tumor. It is generally stated that intrathoracic goiters move on swallowing. This has not been my experience in all cases. Carcinoma with surrounding

Fig. 6—Partial intrathoracic goiter preoperative compression and deviation of the trachea.⁴¹

infiltration, a narrow connecting stalk between the thoracic and cervical goiter and fixation at the inlet all tend to immobilize the intrathoracic shadow under the fluoroscope.

The prognosis of intrathoracic goiter is, in brief, that of nodular goiter developing within the superior mediastinum. The tendency of nodular goiters to become toxic, to grow, to become acutely enlarged by hemorrhage, to become cystic, to become inflamed and to develop carcinoma have been considered as indications warranting their removal. These changes are accentuated in consequence when the goiter lies among the vital structures of the superior mediastinum. Strumitis with resulting adhesions is more frequent in endemic regions. It occurred in 48 per cent of the Berne cases. Malignant changes occur in between 2 and 3 per cent of the cases, although Wuhrmann's original figures were much higher.

I have discussed elsewhere⁴³ the usual occurrence of degenerative changes within the blood vessel walls of nodular goiters. In intrathoracic goiter, as the result of mechanical interference with the return circulation, capillary dilatation occurs and even becomes cavernous hemangiectasia.⁴³ Calcification is frequent⁴² (fig. 1). Arteriosclerosis independent of the generalized form, as well as hyaline change, is common in the thyroid arteries of nodular goiters even in young persons. These degenerative changes predispose to hemorrhage and consequent cyst formation. Evidence of hemorrhage is found in nearly all nodular goiters. It may be interstitial, however, it usually occurs in the nodules

and cysts. The occurrence of acute apoplexy is well recognized. It rarely leads, however, to compression of the trachea severe enough to cause an acute suffocation.⁴⁴ The rupture of the larger sclerosed goitrous vessels resulting in sudden death is likewise infrequent.⁴⁵ Nevertheless, these vascular changes definitely increase the morbidity of nodular goiter.

The operative mortality is very low.⁴⁶ Matth⁴⁷ has reported 219 successive cases without a fatality. It is apparently greater outside of endemic regions, where one contends in addition with a greater incidence of associated severe thyrotoxicosis.⁴⁸ There has been no fatality in our series of cases in which operations have been performed. Carcinoma with bilateral recurrent paralysis and pulmonary metastases was the cause of death in one patient, aged 70 (figs. 3 and 4). In view of our present knowledge of this disease, it would seem wiser to advise the removal of an intrathoracic goiter while it is still to be readily luxated rather than submit the patient to the nodular possibilities plus those eventual changes leading to an increase in the difficulties of excision.

The treatment of intrathoracic goiter is essentially surgical. Luxation and excision is the common procedure and was employed in all our cases. As the goiter grows into the thorax it pushes ahead of it cervical and later intrathoracic fascia and forms in most cases a condensed fascial envelop about the true thyroid fascia and capsule. It maintains its blood supply from above and rarely makes secondary vascular connections of any magnitude through the surrounding fascia. The recognition of these facts is of the greatest importance in the surgical removal. It is of advantage to aspirate cysts. When the goiter is adherent or larger than the thoracic outlet, portions have first been removed from the center (evisceration, Kocher). When morcellement is done and goitrous tissue left behind, there occurs a draining sinus of long duration until finally the necrotic tissue is passed.⁴⁸ The sternum was formerly split its entire length to facilitate removal of larger intrathoracic forms.⁴⁹ Resection of the manubrium and anterior mediastinotomy have likewise been practiced.⁵⁰ Experience has shown, however, that a simple notching of the manubrium to the depth of 5 or 6 cm is nearly always sufficient.⁵¹

Fig. 7—Partial intrathoracic goiter resection of trachea to normal eight and one half months after excision.

The x-rays have been used in the treatment of intrathoracic goiter with varying results.⁵² Since practically all intrathoracic goiters are nodular and since cystic degeneration and

calcification, together with marked vascular degenerative changes, are so frequent, they are as a rule refractory to irradiation.⁹

That the trachea is deviated and compressed by intrathoracic goiter (figs 5 and 6) was recognized long before the advent of the x-rays.⁵ Excision of the goiter results in an immediate and often remarkable improvement in the condition of the patient. Mention has been

Fig 8—Partial intrathoracic goiter; return of trachea to normal eight and one half months after excision.^{1,2}

made of changes occurring in the position of the deviated trachea following thyroidectomy.¹³ However, it is apparent that the return of the trachea to normal following the removal of the deviating goiter is not generally known. As a consequence, it has been of interest to follow the trachea roentgenologically in a number of cases after the thyroidectomy. I have yet to see a case in which it failed to return to its approximate normal position. This is demonstrated in figures 5, 6, 7 and 8. Needless to state, there have not been any cases of severe tracheomalacia.¹⁸ Within ten days following operation, the trachea has already definitely returned toward its normal position.

SUMMARY

Total and partial intrathoracic goiter is frequently unrecognized owing to the fact that a roentgenogram is not made of the trachea. It is nearly always nodular, frequently cystic, and its vessels usually reveal degenerative changes and associated hemorrhage. The prognosis is that of nodular goiter developing within the superior mediastinum. The treatment is surgical removal and it is of advantage to practice this before the goiter has become too large, adherent or even malignant. The cases should be individualized. The operative mortality is very low. The compressed and deviated trachea returns to its normal position following the thyroidectomy.

TUMORS OF THE PARATHYROID GLAND *

CLARENCE G. TOLAND, M.D.
LOS ANGELES

During recent years the parathyroid glands have come into rather special prominence owing to their apparent functional connection with calcium metabolism and tetany. In consequence, parathyroid tumors, instead of being pathologic curiosities, have assumed a more important clinical rôle. I have recently observed two cases of these fairly rare tumors, but before giving the details I will give a short synopsis of the present clinical aspects of the parathyroids and their pathology.

The parathyroids were first accurately described in 1880 by Sandstrom,¹ who apparently, however, held the view that they were undeveloped embryonic thyroid tissue.

In 1898, Gley² showed that tetany following parathyroidectomy did not occur unless the external parathyroids were removed, although they were still considered as part of the thyroid gland.

The parathyroids may be intrathyroid or extrathyroid. According to Guleke³ the human parathyroid may occur in three types: (1) the compact type, as seen in the fetus, (2) the reticular and (3) the lobular. The two latter are seen in adults, but all three types may be observed in the same individual.

FUNCTIONS OF THE PARATHYROIDS

That the parathyroids have a vital function is admitted since their complete extirpation results in tetany and death. When apparent extirpation has not produced death, it has been found that accessory parathyroids were present. The occurrence of accessory parathyroids is not uncommon.

Fig 1—Diagram in ventral view of the pharynx and pharyngeal pouches showing the origin of the thymus and thyroid glands and of the epithelial bodies (modified after Groschuff and Kohn). I, II, III, IV, and V first, second, third, fourth, and fifth pharyngeal pouches.

Present knowledge of the functional importance of the parathyroids may be said to have begun with the researches of MacCallum and Voegtlin,⁴ published in

Read before the Section on Surgery, General and Abdominal at the Fifth First Annual Session of the American Medical Association, Detroit, June 25, 1930.

4 MacCallum, W. G. and Voegtlin, Carl, *On the Relation of the Parathyroid to Calcium Metabolism and the Nature of Tetany*, *J Biol Chem* 19 51 1921

1908 They showed that removal of the parathyroids in dogs resulted in hypocalcemia in the urine and feces. Other investigators showed later that the metabolic changes, apparently governed by the parathyroid secretion, not only included lowered serum calcium but diminished excretion of phosphorus. Tetany was due to the diminished calcium content of the blood serum.

Fig 2—A reconstruction of the thymus and thyroid. The thymus lies in front behind the left innominate vein. *thyr* thyroid, *thym* thymus, *par IV* parathyroid of fourth pouch, *par III* parathyroid of third pouch, *pyr* pyramidal lobe of thyroid, *c a.* carotid artery, *j v* jugular vein.

Further proof of the importance of the parathyroid hormone in calcium metabolism was furnished by Collip⁸ and others, who showed that the injection of parathyroid extracts in parathyroidectomized dogs led to a definite mobilization of calcium in the blood stream, even if the calcium had to be depleted from other tissues.

So far as present knowledge goes, at least one, if not the most important, function of the parathyroid secretion is to maintain the serum calcium level of the blood at a constant threshold.

PARATHYROID TUMORS

Although what were undoubtedly parathyroid epithelial tumors were described by Wolfer under the name of fetal adenomas and by Kocher under the name of glycogenous goiters, DeSanti⁹ was the first, in 1898, to refer to them distinctly as parathyroid tumors.

It follows from what has previously been said that any hyperplastic or neoplastic increase of parathyroid tissue might be expected to be followed by important metabolic functional changes and, therefore, such tumors become clinically important.

According to Langhans¹⁰ classification, parathyroid tumors, which are almost always adenomas, may be divided into (1) intrathyroid parathyroidomas, i. e., when the parathyroid occurs within the thyroid, and (2) extrathyroid parathyroidomas. The first corresponds to Wolfer's fetal adenoma and the second to Kocher's glycogenous goiter.

The histologic characters of parathyroid tumors allow of their clear differentiation from epithelial tumors of the thyroid since parathyroid epithelium is well differentiated from that of the thyroid.

Pure parathyroid hyperplasia, as distinct from adenomatous growths, undoubtedly occurs frequently, especially when one or more of the parathyroids are absent or fail to function. It is a question whether some of the reported cases of parathyroid tumor were not really compensatory hyperplasias. It is not always easy, even histologically, to distinguish between hyperplasia and adenoma, especially when the latter is atypical. In such cases the tissue may perhaps be determined by other clinical evidence, such as osteomalacia. This does not mean that osteomalacia is by any means usual or to any important degree associated with parathyroid enlargement but only that occasionally such an association or some other bone abnormality may be found, as in cases reported by Schlagenhauser⁸ and Harbitz.⁹

Also, a compensatory parathyroid enlargement may follow removal of one or more glands, as in the case reported recently by Guy.¹⁰ In this case, ten months after the removal of an adenomatous parathyroid, nodular swellings appeared in the position of the other parathyroids, which the author ascribed to compensatory hyperplasia rather than to metastases.

A parathyroid adenoma may become malignant. If intrathyroid, the only question that arises is one of differentiation from a particular type of malignant tumor of the thyroid which Langhans has termed a proliferating struma. This similarity has been noted also by Kocher and other investigators. Fasiani¹¹ states that Langhans considered that the parathyroid tumor could be distinguished by the presence of distinct canals with glycogen-containing cells now known as Knustner's canals.

Fig 3—Carcinoma of parathyroid gland under low power. Cellular areas composed of irregular atypical cells. In the centers of these cellular areas are clear spaces (possibly colloid). The cellular areas are separated by a rather wide strip of reticular tissue which composes the stroma. Many nuclei are hyperchromatic. The section lacks orderliness and arrangement and shows the characteristics of malignant changes.

STATISTICAL DATA

Berard and Alamartine¹² in 1909 collected reports of twenty-nine cases (including one personal case) of parathyroid tumors from the literature. This number

has more recently been increased to forty by Pepere¹³ Of Berard and Alamartine's twenty-nine tumors, twenty-four were pure parathyroid adenomas and five were mixed, i. e., containing thyroid and parathyroid epithelium Sixteen were intrathyroid and thirteen were extrathyroid in situation Of the twenty-nine, a few (six) had passed unperceived during life and

Fig 4—Carcinoma of parathyroid gland under high power. Irregular atypical cells of various sizes and shapes. The nuclei are quite large and there is noted in many nuclei a large deeply staining nucleolus. The section is quite cellular with an admixture of a moderate amount of stroma between the thickly cellular areas. The cells are arranged in haphazard fashion. Mitotic figures in this section are hard to distinguish definitely.

were found at autopsy, in fourteen the tumor was the only symptom, in nine there were symptoms of compression. Five of the tumors were undoubtedly malignant with ganglionic, visceral or osseous metastases.

Fasiani has recently reported a case of malignant parathyroid tumor, the size of a fist, invading the left lobe of the thyroid in a woman, aged 65. He gives detailed histologic observations. Preoperatively this suggested a malignant thyroid tumor and postoperatively its nature was established only by the histologic investigation. This tumor was distinguished by a richness of chromophil cells both disseminated and massed or in strings. He did not distinguish Kursteimer's canals. Fasiani believes that this tumor arose from an inclusive parathyroid or from rests of parathyroid tissue in the thyroid.

Fasiani says that only eight cases of malignant parathyroid tumors are reported in the literature. This of course, refers only to primary malignant tumors not to metastases from malignant growths elsewhere such as in the two cases reported by Thompson¹⁴ following carcinoma of the breast and of the neck region respectively. Ferrero and Sacerdote¹⁵ in 1925 reported a case of parathyroid tumor with metastases in the right femur and in the right temporal bone.

REPORT OF CASES

CASE 1—A woman aged 60 had noted a thyroid enlargement for eight years. This became painful and increased rapidly in

size following an attack of acute pharyngitis, three months prior to admission to the hospital. Obstructive symptoms, such as dyspnea and dysphagia, developed. She gradually lost weight. An increasing pallor was noted. She had no thyrotoxic symptoms. The examination revealed some obesity, but was essentially negative. The neck showed a large mass involving the upper pole of the right lobe of the thyroid. This was red and tender. At operation this mass in the neck was found to be densely adherent to the muscles. The mass and entire right lobe of the thyroid were removed. The pathologic report showed adenocarcinoma of the parathyroid. The patient received postoperative irradiation and died four months later from pulmonary metastasis.

CASE 2—A woman, aged 42, had had a subtotal thyroidectomy nine years prior to admission. Six years later she developed a recurrent goiter on the right side. This gradually increased in size and produced pressure symptoms, such as dyspnea and dysphagia. There were no thyrotoxic symptoms. The general health was good. The weight gradually increased.

Examination showed a large recurrent goiter involving the upper pole of the right lobe of the thyroid.

At operation the goiter was found to be firmly adherent. A resection of the right lobe was done.

The pathologic report showed an adenoma of the parathyroid and an adenomatous goiter of the fetal type.

The patient's convalescence was uneventful but she died eight months later following an operation for myosarcoma of the uterus.

902 Wilshire Medical Building

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS CURTIS AND TOLAND

DR RUSSELL M WILDER, Chicago. If the goiter can be palpated there is little danger of mistaking it, but occasionally it lies so deeply and is so completely separated from the cervical thyroid that it fails to rise when the patient swallows. The deepest intrathoracic goiters have so much room in the capacious thoracic cavity that they may cause no pressure symptoms at all. In such a case one must be on guard or the diagnosis will be missed. Like other tumors of the upper and anterior mediastinum, these masses may give rise to a sign to which, I think, Dr Middleton was the first to call attention. This is, namely, a tracheal quality to the breath and whispered

Fig 5—Gross specimen in adenoma of parathyroid

voice sounds heard when the bell of the stethoscope is applied to the manubrium of the sternum. The sign is analogous to d'Espine's sign posteriorly when the mediastinum is filled with large tuberculous lymph nodes or other tumors. Normally one hears a bronchovesicular respiration over the manubrium but when a solid mass displaces the margins of the air-filled lungs the bronchial sounds are transmitted directly to the ear and these are almost as loud as the sound obtained when the stethoscope is placed on the neck directly over the trachea. I have recently reexamined the patient whose case of hyperparathyroidism was reported from the Mayo Clinic in May, 1929. This was an instance of diffuse fibrous osteitis associated with an adenoma of the parathyroid. It is now eighteen months

since this tumor was removed. The immediate results of the operation were dramatic as has been true of all the cases reported heretofore. The hypercalcemia was immediately arrested, as was also the large urinary excretion of calcium. The patient's strength improved rapidly, so that within two weeks she was able to abandon crutches and walk with the help of a cane. She was seen again in April, 1929, and improvement seemed to be continuing. She had shortened in stature 2 cm, which was attributed to her being on her feet

Fig 6—Adenoma of parathyroid under low power. This section shows the cells arranged in irregular groups or cords and in some places what appears to be round tubules. The nuclei are fairly good sized and the chromatin takes a dark stain.

while the skeleton was still soft. At the present time her condition is only fairly satisfactory. She is not strong and generally uses a cane, although able to walk without it. She has some pain in the bones of her hands, feet and shoulders but not, as formerly, in other bones. She has shortened another 4 cm and weighs less than she did at the time of operation. The calcium and phosphorus of the blood are normal, and a twenty-four hour specimen of urine contained only 140 mg of calcium, which seems normal. Roentgenograms of her bones still reveal considerable porosity but no cysts. The density of the bones is, however, still far from normal. The patient was taking calcium phosphate and cod liver oil until some time in November, and when she discontinued these the general strength apparently diminished. My general impression is that this patient is still suffering, to a lesser degree, from the original disease. This may be due to another tumor, or there may now be an overfunction of the remaining parathyroid glands, or the question may be less simple than it seemed at first and the relationship of the parathyroid to the bony abnormalities less definite than was thought.

DR HOWARD M. CLUTE, Boston. Our experience in the Lahey Clinic with possible parathyroid tumors has been limited to one recent case. Clinically there was a parathyroid tumor, but microscopically the specimen removed was not positively parathyroid in origin. Clinically, however, it may be said to have been a parathyroid tumor because there was extreme muscle weakness, a marked porosity of the bones of the skeleton, and a marked hypercalcemia. It is obviously a most rare condition. In this instance removal of the tumor was not followed by ultimate recovery, since the patient died with multiple malignant metastases. In intrathoracic goiter, the position of the trachea is one of the most important things. One particular type of intrathoracic goiter to which I would call attention is the retrotracheal goiter which descends behind the trachea and pushes the trachea well forward. It may be present and undiscovered if a lateral view is not taken. The pressure symptoms which Dr Curtis has mentioned are the outstanding symptoms of importance in substernal goiters. The last thing to be mentioned is the danger of mediastinitis post-operatively. The cavity from which the goiter comes must be

drained adequately and thoroughly. We have found from experience that the drains must not be removed too early after operation. If they are, fluid collects in the superior mediastinum, with resulting infection in many cases, with difficulty in swallowing, and with fever. When this occurs, marked widening of the mediastinum and a definite beginning mediastinitis results. Mediastinitis is a dangerous complication. In this particular instance, the neck was reopened and thorough drainage of the mediastinum instituted, with ultimate cure as the outcome.

DR FRANK H. LAHEY, Boston. Intrathoracic goiter is not limited to the region where goiter is endemic. Among 8,500 patients operated on for goiter, we have had about 250 intrathoracic goiters. In intrathoracic goiter one should be careful about two points. 1. Pieces should never be left behind. The blood supply of intrathoracic goiters comes from above, the superior thyroid artery and the inferior thyroid artery, and if nearly all of the intrathoracic goiter is removed but a segment is left unvascularized below, the very things have been accomplished which will predispose to mediastinitis, fluid, necrosis and infection. If there is any infection there will be mediastinitis. If mediastinitis exists, nothing in the world in our experience, drainage, irrigation or anything else, will influence it. Mediastinal cellulitis has gone on always to a fatality. 2. The best approach technically to intrathoracic goiter is from the back of the tumor. One should not try to get into the mediastinum from in front. A pathway has already been established in back by the large vessels of the neck, and along this path of the common carotid and the internal jugular is a passage where the finger readily passes. Then the intrathoracic goiter may be separated from its surrounding layer of connective tissue, mobilized, and removed from above. The best anesthesia in our experience with these patients with intrathoracic goiter who have respiratory difficulty is a form of gas anesthesia with a tight face mask. We have occasionally had very trying times in the delivery of these large tumors through the narrow superior thoracic strait, and at that time the anesthesiologist with gas-oxygen or ethylene by pressure on the bag with a tight mask, can supply these patients with sufficient oxygen so that one has several minutes of manipulation in which to deliver this large tumor through the small upper

Fig 7—Adenoma of parathyroid under high power. The cells here are arranged in compact groups and cords with a thin stroma in between. The cytoplasm is clear. The chromatin of the nuclei takes a dark stain.

thoracic aperture, during which time the trachea is completely collapsed. Dr Clute has brought out a valuable point, which is the necessity of prolonged drainage. Because this is a large cavity which requires a long time to collapse, fluid readily reaccumulates and readily becomes infected. The later it accumulates, the less likelihood or the dangerous and fatal complications which must always be guarded against: mediastinitis. These large intrathoracic cavities often require two or three weeks of drainage.

HYPERPARATHYROIDISM

THE CLINICAL PICTURE IN THE FAR
ADVANCED STAGE*ARMAND J. QUICK, PH.D., M.D.
AND
AMBROSE HUNSBERGER, JR., M.S.
PHILADELPHIA

It is well known that when parathyroid extract, the active principle of the parathyroid gland, is injected into an organism, hypercalcemia is produced. If these injections are continued a negative calcium balance results, with ultimate decalcification. This is followed by the formation of fibrous bone lesions, as Jaffe, Bodansky and Blair¹ have recently shown. That a condition similar to this experimental hyperparathyroidism could exist clinically was not clearly recognized until Mandl² in 1926 removed a parathyroid tumor in a case of generalized osteitis fibrosa cystica and thereby effected a prompt and apparently permanent clinical improvement. This suggested that the causative factor of osteitis fibrosa cystica was a hyperactive parathyroid. The correctness of this conclusion has been fairly well established by a series of other cases reviewed by Barr and Bulger,³ and correlated under the term "clinical hyperparathyroidism." In this paper we are presenting another case of osteitis fibrosa cystica in which a large physiologically active parathyroid tumor was found and removed. The pathologic process had advanced to such a stage that some of the bones appeared to be almost completely demineralized. The same case was reported under the title "Multiple Giant Cell Tumors" by Alexander and Crawford⁴ three years ago when the clinical syndrome of hyperparathyroidism had not been recognized. In the light of present knowledge, the patient showed at that time the typical picture of early hyperparathyroidism.

REPORT OF CASE

J. M., a white man aged 25 admitted to the Philadelphia General Hospital, June 30, 1929, had extreme deformities of almost every portion of his skeletal system except the hands, feet and head, but was free from pain and other distressing symptoms.

His family history was negative. His personal and past history, prior to the appearance of symptoms that are definitely a part of his present disease are of no especial significance. Before the onset of the present symptoms he was a well developed youth, 6 feet tall, and weighing about 200 pounds (fig. 1). He was born in the mill district of Philadelphia and at the age of 14 started working in a hosiery mill. With the exception of three months in 1925, when he was in the United States Navy, he remained a mill worker until his present condition compelled him to stop work. While in the navy he received a blow over his right jaw while boxing. This produced a moderate sized swelling which persists even now, but never progressed. The patient never used alcohol or tobacco was regular in his habits and gave no history of venereal infection.

4. Alexander F. C. and Crawford W. H. Multiple Giant Cell Tumors. *Ann. Surg.* 86: 62 (Sept.) 1927.

The first intimation of the present illness was in January, 1925, when he suffered a ruptured right ligamentum patellae as the result of a fall and was operated on at the Episcopal Hospital. A roentgenogram of his knee taken at that time showed beginning bone changes. Soon after his discharge from the hospital he began to notice a marked polydipsia and polyuria, with milky urine. (It was probably at this time that he was excreting large quantities of calcium at the expense of his osseous system.) Soon after this he began to experience severe sharp shooting pains in his back, arms and legs. The pains were not relieved by medicine. Because of these pains and persistent nausea, which at this time he attributed to the odor of the hosiery dye he quit his job in August, 1926. His nausea, however, persisted. In October, 1926, while taking a bath he had a spontaneous fracture of his left femur, and in falling sustained further fractures of his right femur and right humerus, which were treated at the Episcopal Hospital. Roentgenograms taken at that time disclosed a generalized pathologic condition of the bones. "There is a generalized fibro-cystic osteitis with an atypical appearance in the different

Fig. 1.—The patient at the age of 17 years.

regions, which in the distal end of the radius and the lower end of the left femur has advanced to that of a giant cell tumor. In the regions of the elbow, it has the appearance of a chronic osteomyelitis. In the right femur the appearance suggests strongly the possibility that the process has undergone a sarcomatous degeneration.⁴ On physical examination, however, he showed very little. There was a swelling of the lower end of the left radius. A paralysis of the left true vocal cord was also noted, which was attributed to an anesthetic given eighteen months previously. While he was in the Episcopal Hospital biopsies were taken from the lower end of the left radius of the left ulna and the lower end of the right femur.

In each case the pathologic report was that of giant cell tumor. The right humerus showed excellent callus formation 100 days after the fracture. Significantly the blood calcium at this time was 15.4 mg. and the blood phosphorus 2.1 mg. He was discharged from the Episcopal Hospital May 16, 1927. While at home his deformities became progressively worse and multiple swellings over various bones appeared. In spite of his deformities he felt well except for a severe epistaxis which required medical treatment. During this period he had one attack of hematuria.

At the time of his admission to the Philadelphia General Hospital in June, 1929, he was in fairly good health. His cardiorespiratory system was entirely normal, except for a slight degree of dyspnea caused by the deformity of his thorax. His appetite was good, he had no digestive trouble, no constipation or diarrhea and no abdominal pain. He had, however, frequency of urination and moderate nocturia but no renal colic.

The patient remained in the orthopedic department until January 1930 when through the courtesy of this department he was transferred for further study to the medical ward service of Dr. Schnabel. During the first six months in the hospital his condition remained essentially unchanged. No

attempt was made to correct his deformities since the roentgenograms revealed such a degree of demineralization of bone that any corrective procedure seemed futile.

Physical examination showed extreme deformity. With the exception of his head, hands and feet, every portion of his skeletal system was distorted and misshapen (fig 3). The contraction deformities had reduced his total length to 45 inches from his original height of 70 inches. There was a pronounced bulging of the thorax and both legs just below the knees were bent sharply outward, producing a typical frog-leg appearance. He was, however, relatively well nourished and had no cough, cyanosis or anemia. Respiration was somewhat rapid and shallow because of the deformity of the chest.

The head was normal except that the percussion note over the calvarium was rather flat as compared with the more metallic quality of the normal skull. There was a swelling of the right maxilla the size of a small olive about half an inch anterior to the angle of the jaw.

The ears and nose were normal.

Ophthalmoscopic examination of the eye showed normal retinas, disks and blood vessels.

Examination of the mouth showed the hard palate to be unusually low and flat. The teeth were in fair condition but somewhat loose, and there was a moderate amount of pyorrhea.

There was unusual shortness of the neck because of the deformity of the cervical spine. No rigidity or impairment of motion was noted. On the left side anteriorly there was a fullness the proper significance of which could not be fully evaluated because of the general distortion of structures in this region. Just anterior to the sternocleidomastoid muscles and immediately above the sternoclavicular articulation there was

Fig 2—Left elbow showing beginning bone changes. Biopsy taken from the indented area March 25 1927 was diagnosed as giant cell tumor.

a freely movable hard mass, about 15 mm in diameter. This was at first overlooked and was noticed only a short time before the operation.

The most prominent deformity of the thorax was due to the extreme bulging of the sternum at the angle of Louis. The lower portion of the sternum flanked by the costal margins formed a flat triangle that sloped toward the abdomen at an angle of 45 degrees. The flaring of the costal margin was more prominent on the left, thus increasing the distortion and asymmetry of the chest. The circumference of the thorax at the level of the nipples was 39 inches and the maximum expansion was less than 1 inch. There was a striking lack of fixation and stability of the thoracic cage allowing a rotation of several degrees.

There was a marked kyphosis at the level of the mid-dorsal spine.

Because of the deformity of the chest no satisfactory examination of the heart and lungs was possible but grossly no signs of pathologic changes could be found. There was no arrhythmia but a moderate tachycardia. Blood pressure was 110 systolic and 90 diastolic on the right arm, 130 systolic and 105 diastolic on the left arm. The peripheral arteries were somewhat sclerosed.

As a result of posture, there was a moderate protuberance of the abdomen especially below the umbilicus. The prominent striae were indicative of the marked decrease in the size of the abdomen. The liver could be felt below the costal margin but probably was not enlarged. The bony pelvis was deformed and there was a pronounced irregularity of the iliac crests.

The left arm showed a marked bowing of the humerus, a swelling of the head of the radius and a thickening of the

wrist. The hand, which was relatively normal, was bent toward the ulnar side. There was a clubbing of the fingers of both hands. The arm could be raised to an angle of 45 degrees, motion in the elbow joint was nearly normal, pronation was about one-third complete, and the motion in the wrist was little impaired. Since the position of the arm was good and since the patient could bring the left hand to his face, this extremity was of the utmost usefulness and importance.

In the right arm the humerus was markedly deformed and there was a swelling at its lower end. The upper end of the ulna was also thickened and the radius was very irregular. The

TABLE 1—Results of Treatment

7/7/28	8.9	4.2			

arm could be raised only a few degrees, the elbow was fixed, the power of pronation was lost and the motion of the wrist was very limited.

The right leg showed a marked shortening and bowing of the femur so that the total length of the thigh was only 12 inches. There was furthermore a twisting of the femur, so that the knee was situated on the outer lateral side. About 4 inches below the knee the leg was bent sharply forward and outward. Motion in the hip joint was little impaired, but motion in the knee and ankle was nearly absent. The foot was relatively normal.

In the left leg the femur was distorted, thickened, bowed and shortened, the total length of the thigh being 13 inches. Just below the knee the leg was bent outward and backward at an angle of 90 degrees. The motion of the hip was good, while that of the knee was somewhat impaired. The foot was fairly normal.

The skin was normal.

An examination of the neuromuscular system revealed no marked muscular atrophy. Reflexes were hard to elicit, but no prominent neurologic signs indicative of a neurologic condition were observed.

The daily volume of urine was about 2000 cc. the specific gravity was fixed, the variation in the Mosenthal test being between 1.009 and 1.012. In reaction the urine was acid and

showed a trace of albumin, but no casts, sugar nor Bence Jones albumin were found

There was a persistent leukocytosis ranging between 16,000 and 18,000, of which 70 per cent were polymorphonuclears. No abnormal blood cells were observed. The red cell count was 4,250,000, hemoglobin, 13.6 Gm per hundred cubic centimeters. The bleeding and clotting time were two and four minutes, respectively. The blood Wassermann reaction was negative.

Chemical examination of the blood showed sugar, 87-118, urea nitrogen, 12-21, nonprotein nitrogen, 42, uric acid, 5, cholesterol, 130, and sodium chloride 488, expressed in milligrams per hundred cubic centimeters. The carbon dioxide capacity was 50 per cent by volume. Blood calcium was consistently high before operation (table 1). Plasma phosphatase (10) was increased from four to five fold. Calcium balance studies indicated an increased positive balance after the second operation (table 2).

It was not possible to determine the basal metabolic rate because of the difficulty of computing the true surface area

The vital capacity was 1180 cc. The phenolsulphonphthalein output in two hours was 15 per cent. The electrocardiogram was normal except for a slight left axis deviation.

The roentgenographic report of July 2, 1929, by Dr. E. Burvill-Holmes stated that there was a marked decalcification of all the bones of the body with innumerable fractures. Both femurs were broken in several places and almost completely demineralized. The ribs, tibiae and metacarpals showed numerous fractures. The bones generally showed a more or less cystic appearance and in some areas showed definite evidence of giant cell tumors. There was a well marked giant cell tumor occupying the head and distal fourth of the left radius (fig. 4). The upper portion of the ulna also showed a giant cell tumor. Growths were evident also in the proximal

third of the ulna and more so in the proximal half of the shaft of the radius. Another large tumor growth above the condyle of the right humerus was noted. Over the site of the left kidney there were three discrete dense circumscribed shadows, approximately 12 mm in diameter, which might possibly be areas of calcification within this organ. The diagnosis was fibrosing osteitis in conjunction with giant cell tumors. The roentgenogram taken Feb. 5, 1930, showed further decalcification (fig. 5).

The diagnosis of hyperparathyroidism seemed so obvious that an exploratory operation seemed definitely indicated. Furthermore, Dr. E. L. Eliason, who was called in consultation, noted a fulness on the left side of the neck that was suggestive of a tumor. Three weeks prior to the operation the patient was given thirty drops of viosterol⁵ daily as a preoperative preparation to prevent a too rapid fall of serum calcium after the removal of a possible parathyroid tumor.

The first operation was performed by Dr. Eliason, Feb. 28, 1930. Owing to the extreme shortness and deformity of the neck, it was difficult to get adequate exposure. This was further complicated by the fact that the operation had to be done under local anesthesia, since the low vital capacity made it inadvisable to use general anesthesia. An oblique incision was made over the fulness on the left side of the neck, and the left lobe of the thyroid was exposed. On exploring its under surface an encapsulated mass, the size of a small olive was found. An attempt was made to remove the mass with

Fig. 3—The patient at the age of 26 a few days before the removal of a hyperplastic parathyroid tumor.

the capsule intact but unfortunately the capsule ruptured and hemorrhage resulted. Only the main central portion of the mass was enucleated and removed while the capsule which probably contained hyperplastic parathyroid tissue, was sutured together to stop bleeding. The wound healed rapidly by first intention.

The pathologic report on the tumor by Dr. W. H. Blick was to the effect that it was an irregular rounded mass 1.7 by 1.5 by 1.1 cm, which appeared to have been shelled out of a capsule. The surface was grayish and was pitted. On section a mottled grayish cut surface was seen which showed fine yellowish dots and exuded blood at numerous points.

Microscopic examination of a section through the mass at the level of the greatest diameter showed a uniform structure characteristic of the parathyroid and made up of anastomosing solid cords of epithelial cells arranged in more or less palisade fashion. The tissue was very cellular and showed scant supporting connective tissue stroma. The cells were proliferating actively and the stroma was extremely vascular even hemorrhagic in places so that the whole picture was one of marked hyperactivity of the gland. There was no evidence of a malignant condition. The diagnosis was hyperplasia of the parathyroid.

Since the patient showed few symptoms before operation no striking clinical result could be expected. His serum calcium

⁵ Supplied through the courtesy of Mead Johnson & Co., Inc.

dropped immediately from 147 mg two days before operation, to 13 mg twenty-four hours following the removal of the tumor, and in one week fell to 11.5 mg. Subsequently, the calcium again began to rise slowly. Since this was considered to be due to residual hyperplastic parathyroid tissue, superficial roentgen therapy was tried. The results were unsatisfactory. The serum calcium steadily increased and in three months was again over 15 mg. per hundred cubic centimeters.

June 5 Dr. Ellison performed a second operation. Somewhat inferior and deeper than the first tumor an encapsulated mass was found which in all probability was a portion of the original

studies showed that there was retention of relatively large amounts of calcium. At the present time attempts are being made to correct some of the skeletal deformities.

COMMENT

The case under discussion emphasizes the great importance of recognizing early the condition of hyperparathyroidism. The patient, who at the age of 21 presented a picture of unusually perfect physical development, was reduced in the course of three years to the state of a helpless cripple and is now so deformed that any extensive corrective procedures seem futile. The history is instructive, for most of the cardinal signs and symptoms that characterize hyperparathyroidism, in both early and late stages, have been exhibited.

The earliest sign presented was a swelling of the right mandible following a traumatic injury. Whether this was a solitary bone cyst and whether it was related to his present disease cannot be answered with certainty, but it is probable that it was the earliest manifestation of the disease. The first definite symptoms were polydipsia, polyuria, a persistently milky urine, and sharp myositic and arthritic pains. It is highly probable that polyuria is often a definite symptom of early hyperparathyroidism, for the hypercalcemia, like the hyperglycemia of diabetes, causes a disturbance of the osmotic relationships which results in a marked increase in the volume of urine. A distinctly milky appearance of the urine would exist only in those instances in which the output of calcium is excessive, as in this case. Myositic and arthritic pain has been the most common symptom and was present in most of the reported cases. In some cases, notably the one described by Hunter,⁶ there was marked bone tenderness. It should be remarked that, in our patient, pain was pronounced in the early part of the disease and now is practically absent. Nausea and vomiting also were early symptoms, which later disappeared entirely. While hypotonia and muscular weakness have been pronounced in several of the cases, in this patient the muscles are surprisingly well preserved and one gets the impression that much of the deformity of the

Fig. 4—Appearance of left elbow July 2, 1929, twenty-seven months later than roentgenogram shown in figure 2. A large giant cell tumor has formed at the level of the radius.

tumor. It was not possible to remove the mass intact. The main portion was enucleated and the remaining tissue was carefully removed by means of a curet.

Pathologic examination disclosed that the specimen consisted of several fragments of light yellowish tissue, the largest of which was partially encapsulated and measured 3.5 by 2 by 1.5 cm. Microscopically the picture was essentially the same as that seen in the previous section except that the cells showed even greater hyperactivity. The increased stroma of the gland and the irregularity of the size of the cells suggested the possibility of early malignant changes.

Following the second operation, a rapid drop of serum calcium occurred. Two days previous to the operation the serum calcium was 15.3 mg. per hundred cubic centimeters, and twenty-four hours after the removal of the tumor, it decreased to 8.9 mg., and in forty-eight hours, to 6.5 mg. On the third day, the lowest value, 5.5 mg., was obtained. In spite of this low calcium concentration, the patient had no symptoms of tetany, except a slight tingling sensation in his extremities, which he described as a 'feeling of electricity'. He noticed this feeling for a short time on the second evening after operation, and it recurred the following day. On the fourth day signs of tetany appeared. The tingling sensation became more marked, positive Chvostek and Trousseau signs were observed, and there was a mild spasm of the glottis. Intravenous administration of 10 cc. of 10 per cent calcium gluconate relieved the acute symptoms. The following day the signs of tetany returned with increased intensity. One gram of calcium chloride given intravenously, gave prompt relief, but the positive Chvostek sign was not abolished and in the course of a day the tingling sensation and feeling of numbness recurred. On the seventh day he was again given intravenous calcium chloride. On the tenth day he was markedly improved and on the thirteenth day was entirely free from symptoms of tetany.

As soon as the patient developed the first signs of tetany, the oral administration of calcium was begun. Neither calcium gluconate nor calcium lactate appeared as effective as calcium chloride. Viosterol was started one day before the operation and given in large doses (from 30 to 75 drops a day), until the serum calcium was again over 8 mg. After this only five drops a day were given. No parathyroid extract was administered.

Roentgenograms taken one month after the second operation showed increased density of the bones (fig. 7), and metabolic

Fig. 5—Appearance of left elbow Feb. 5, 1930, further decalcification with almost complete disappearance of the head of the radius.

extremities is due to a relative disproportion between the yielding demineralized bones and the fairly strong contractile power of the muscles.

Renal colic, which has been reported in these cases was not observed. It is apt to occur, however, because of calcium stones forming in the pelvis of the kidney as a result of the high concentration of calcium in the urine. Constipation also has been mentioned but probably is an unimportant symptom.

6 Hunter, Donald. Hyperparathyroidism. Hyperfunction of Parathyroid Tumor in a Case of Generalized Osteitis Fibrosa. *Proc. Roy. Soc. Med. Sect. Med.* 23: 227 (Dec.) 1929.

Disturbance of gait and orthopedic deformities, such as genu varum,⁷ genu valgum⁸ and abnormal mobility of joints,⁴ have also been prominent early symptoms.

The symptoms encountered in the far advanced stage are few and surprisingly mild, if this case can be considered representative. The renal insufficiency, as manifested by polyuria and nocturia, and substantiated by urine analyses and kidney function tests, is a serious sequel of the continuous hypercalcemia. Since Hueper⁹ has demonstrated that calcification of viscera results after continued administration of parathyroid extract, and since in one of the patients reported by Barr and Bulger³ metastatic calcification of the kidneys was found, it seems logical to conclude that the kidney deficiency is at least in part due to calcification of parenchymatous renal tissue. This is further substantiated by the fact that in our patient the roentgenograms show calcified nodules in the region of the right kidney. The roentgenograms also show considerable calcification of the peripheral arteries.

The most characteristic laboratory observation in hyperparathyroidism is a persistent hypercalcemia. The calcium values, however, are not constant but are influenced by a number of factors, such as the intensity of the disease, the amount of calcium in the diet, the vitamin D intake, and possibly ultraviolet irradiation. The highest value for serum calcium thus far reported is 23.6 mg per hundred cubic centimeters,¹⁰ but usually in this disease values range between 13 and 17 mg. The serum calcium in the case under discussion varies from 14 to 15.8 mg per hundred cubic centimeters. The lowest value, 14 mg, was obtained when the calcium intake was restricted to 0.74 Gm in twenty-four hours, but on the same diet with the addition of 30 drops of viosterol daily for two weeks the serum calcium was 14.7 mg. Of fundamental importance in hyperparathyroidism is the excessive excretion of calcium, causing a negative calcium balance. In this case, peculiarly, there was no demonstrable loss of calcium when the patient was on a relatively low but theoretically adequate intake of calcium. The slight positive balance which was found does not exceed the possible limit of error, which might suggest that the available supply of calcium had reached such a degree of exhaustion that an equilibrium existed between the intake and the output of calcium.

After the removal of the parathyroid tumor a definite positive calcium balance was established with a marked decrease in the excretion of calcium in the urine. The phosphorus, like the calcium, varied between rather wide limits, but in general the values were somewhat below normal and roughly varied inversely with the calcium values.

The high concentration of plasma phosphatase in osteitis fibrosa is of interest because it may have diagnostic importance. This is an enzyme capable of splitting certain organic phosphates, such as hexosephosphate and glycerophosphate.

Recently Kray¹¹ has reported an increased concentration of phosphatase in plasma in various bone diseases especially in osteitis deformans but also in a case of osteitis fibrosa. The phosphatase value found

in our case was more than four times the normal value.

From the diagnostic point of view the roentgenogram is of utmost importance. Probably most of the cases will be called to the attention of a physician only after a pathologic fracture has occurred or after the patient has noticed swellings over one or several bones. When a roentgenogram is taken, a generalized bone involvement may be discovered. In our case it is fortunate that roentgenographic plates are available, both of the early and of the advanced stage. In the roentgenograms taken three years ago, cysts and swellings diagnosed as giant cell tumors were found and the general picture was that of osteitis fibrosa cystica. The swellings on biopsy further showed the histologic characteristics of a typical giant cell tumor. The benign character of these tumors is vouched for by the long duration of the disease. In the advanced stage of the disease the bones showed such an unusual degree of decalcification that it was difficult to get satisfactory roentgenograms.

Fig. 6.—Section of the parathyroid tumor showing its compact cellular and highly vascular nature.

The bone condition found in generalized osteitis fibrosa cystica should not be confused with the localized form of fibrosa cystica, which may be a distinct clinical entity as pointed out by Mandl.¹²

With the recognition of the importance of parathyroid dysfunction in clinical medicine further knowledge concerning the function of this gland is urgently needed. In spite of the tremendous volume of literature on the physiology of the parathyroids, it appears that the only definitely known function of these glands is to maintain the normal calcium level of the blood. The active hormone of the parathyroid increases serum calcium apparently by the liberation of this element from the bone deposits. There seems to be no evidence to indicate that the hormone can aid in the absorption of calcium from the gastrointestinal tract or render it available for the body; neither is there conclusive evidence that the parathyroid is responsible for the deposition of calcium in bone. Since the parathyroid

seems to be responsible for maintaining the normal calcium level of the blood, it is to be expected that hyperplasia of the parathyroids is apt to occur when there is a depletion of the blood calcium, such as might be brought about by a prolonged calcium-poor diet by pregnancy or by a deficiency of vitamin D in the diet. Both Marine¹³ and Luce¹⁴ have observed this hyperplasia in animals after feeding a diet low in calcium. Probably the parathyroid is not affected by pregnancy and lactation if the mother receives a diet high enough in calcium, phosphorus and vitamin D to supply the needs of the fetus.

Although vitamin D or viosterol, like parathyroid extract, raises serum calcium its action is probably independent of the parathyroid and perhaps even antagonistic to it. Recently Jones, Rapoport and Hodes,¹⁵ and Demole and Christ¹⁶ found that the serum calcium in thyroparathyroidectomized dogs can be raised not only to normal levels but also to values 50 per cent

to assume that vitamin D, by causing absorption of calcium from the intestines, indirectly assists the parathyroid in maintaining the serum calcium level. Should the animal be entirely deprived of the antirachitic vitamin, the whole burden of maintaining the calcium level would fall on the parathyroids, in consequence of which hyperplasia of these glands might be expected. Nonidez and Goodale,¹⁸ and Higgins and Sheard¹⁹ have obtained experimental results that lend support to this conclusion. They found that, when chicks were kept from direct sunlight and fed a diet poor in the antirachitic vitamin, enlargements of the parathyroids resulted. If it is assumed that the action of vitamin D is antagonistic to that of the parathyroid, one can explain the observation that a high vitamin D intake or ultraviolet irradiation produces a symptomatic improvement in osteitis fibrosa. Mandl²⁰ noted that his patient improved in summer, and Wilder²⁰ commented on the favorable action of vitamin D on his patient. In this case even a positive calcium balance was established.

The therapeutic action of vitamin D in hyperparathyroidism is only temporary and cannot cure the disease. It has possibly, however, another use. Barr and Bulger,²¹ as well as others have shown that the most serious danger in removing a hyperplastic parathyroid is the sudden drop in serum calcium, which may cause a severe and even fatal tetany. One patient reported by Beck²² died of tetany in twenty days after the removal of a parathyroid tumor, and only heroic efforts saved the patient of Barr and Bulger. Since Jones, Brougher,²³ Wade²⁴ and Greenwald and Gross²⁵ have found that tetany in thyroparathyroidectomized dogs can be prevented or at least minimized and delayed by the preoperative administration of cod liver oil or viosterol, it seems logical to treat hyperparathyroid cases in a similar way preoperatively. This was done in our patient, but as the tumor was only partially removed at the first operation it is difficult to decide to what extent the slow drop in serum calcium was influenced by viosterol. For the second operation the administration of viosterol unfortunately was begun only one day preoperatively. It seems rather definite that viosterol exerted an unquestionably beneficial effect. Although the serum calcium dropped very rapidly and in three days reached the value of 5.5 mg no signs of tetany, except a slight tingling sensation, were manifested. Although the signs and symptoms of tetany became more marked from the fourth to the ninth day after operation, they were not nearly as severe as one might have expected from the low concentration of serum calcium. Recovery was amazingly rapid, and in less than two weeks after operation no signs of tetany remained, even though the serum calcium was still 5.7 mg. A few days later, however, the calcium began to approach normal values. Other inves-

Fig 7—Appearance of left elbow July 2 1930 one month after the second operation there is a definite increase in the density of the bones the proximal end of the radius is entirely absorbed

above normal by viosterol. Jones¹⁷ has further found that, if an animal is deprived of calcium in its diet, viosterol failed to raise serum calcium. These results suggest that the increase of calcium in the blood after the administration of vitamin D is due to a greater and more complete absorption of ingested calcium. Since it is well known that vitamin D brings about calcification in bone, as in the curing of rickets, one is led to conclude that the action of vitamin D is antagonistic to parathyroid extract, which liberates calcium from bone, although both raise serum calcium. In fact it is logical

tigators, Brougher,² Gleich and Goodman,^{2*} and Stein,^{2*} also have found vitamin D effective in relieving parathyroid tetany in human beings. Although vitamin D can raise serum calcium, its action in preventing tetany does not seem to depend primarily on raising the concentration of calcium. Vitamin D, furthermore, probably aided recalcification, for in our case a definite increase in the density of the bones was noted in the roentgenograms one month after the second operation, and metabolic studies showed a pronounced positive calcium balance.

SUMMARY

In an extremely advanced case of hyperparathyroidism (osteitis fibrosa cystica), a parathyroid tumor was found, and after its removal marked improvement was noted.

The importance of early diagnosis is emphasized and a review made of the most common early symptoms and laboratory observations.

The relation of vitamin D to the parathyroid is discussed. The use of viosterol is advocated for preventing or minimizing parathyroid tetany, and also for hastening the recalcification of bone after the removal of a parathyroid tumor.

TREATMENT OF GANGRENE DUE TO THROMBO-ANGIITIS OBLITERANS*

SAUL S. SAMUELS, M.D.

NEW YORK

The past decade has witnessed radical changes in the treatment of thrombo-angitis obliterans.¹ Former teachings concerning this disease gave rise to the impression that the ultimate outcome in almost every case of thrombo-angitis obliterans was amputation of one or more extremities because of the inevitable occurrence of gangrene. This erroneous idea has been so impressed on physicians that patients, even in the early stages of the disease are often looked on as hopeless, and doomed to a future minus legs and arms. I have known of instances in which immediate amputation of both legs was advised because of the presence of incipient thrombo-angitis obliterans, without ulceration or gangrene. A still larger number of cases of thrombo-angitis obliterans are submitted to high amputation because of the presence of a small area of gangrene limited to one toe. In many textbooks the disease is described as a progressive series of amputations, and, as a result of these teachings the family physician is often misled into believing that once the diagnosis of thrombo-angitis obliterans is made the surgeon should be consulted for immediate amputation of the affected limb. Since the advent of modern methods of diagnosis and treatment of this malady it has become necessary to revise the older concepts of this disease and to adopt a more optimistic attitude as far as its prognosis is concerned.

Before proceeding to a detailed description of the methods I have used in treating this disease I believe it well to describe one case which because of its

severity and unusual outcome, will illustrate the points I wish to emphasize.

REPORT OF CASE

A Russian Jew, aged 32, developed gangrene of the left foot as a result of thrombo-angitis obliterans. At the time of my first examination, the toes of the left foot were completely gangrenous and there was an area of superficial gangrene extending back almost as far as the ankle and the heel (fig 1 A). Oscillometric examination² revealed no pulsation at the left ankle. The gangrene was of the "wet type", that is, the toes and adjacent tissues were macerated and there was considerable infection in the surrounding portion of the foot. There was also marked edema of the lower part of the leg and foot so that the circumference of the ankle was increased to about twice its usual size. This edema was due to the dependent position in which the patient had been maintaining the foot constantly prior to my intervention. The patient's general condition was very bad because of peculiar starvation diets that had been previously prescribed for him under the belief that the disease might be a metabolic disturbance. In view of the extent of the gangrene and of the patient's poor general condition and also because of the severe pain immediate high amputation had been advised. The patient, however, was insistent that he would rather die than undergo the loss of his leg. It was thereupon decided that if there was no increase in size of the gangrenous area after a week's observation conservative measures would be instituted with the hope of producing separation of the gangrenous parts and subsequent healing of the wound. That this attempt was successful is apparent after studying a recent photograph (fig 1 B) taken ten months after the institution of conservative therapy.

CLINICAL CONCEPT OF GANGRENE

In order to interpret properly the clinical picture of a gangrenous process as it is encountered in thrombo-angitis obliterans, one must correlate what one sees externally, with the underlying pathologic changes that are taking place. It must first be realized that not every

Fig. 1.—Extensive gangrenous ulcer. A, after spontaneous amputation of all toes; note exposed head of first metatarsal. B, ten months later showing foot completely healed and covered with epithelium; spontaneous amputation of all toes without surgical intervention.

case of thrombo-angitis obliterans terminates in gangrene. As a matter of fact the percentage of patients with this disease who ultimately develop gangrene is surprisingly small. I have had under observation for the past seven years a patient with occlusion of the main arteries of both legs extending as high as the groin. This patient has not yet developed gangrene. In order to account for this it must be recalled that one of the fortunate peculiarities of this disease is the formation of an extensive collateral circulation coincident with the occlusion of the main arteries. This has been repeatedly demonstrated in roentgenograms of amputated legs the arteries of which have been injected with radiopaque substances. From this it can be deduced

that, as long as the balance between arterial occlusion and formation of collateral circulation is maintained, gangrene will not develop. If, however the balance is disturbed by the sudden occlusion of a large artery or if the reserve collateral circulation is depleted by the extensive use of nicotine or by other agents, it is evident that gangrene will ensue. The most common immediate cause of the development of gangrene is the depletion

logic process of occluding arterial disease is one of self-limitation. When the arterial circulation in the extremity becomes insufficient for life of the part, the severe pain characteristic of dying tissue sets in. At the onset, the pain is felt at the point where the gangrene is about to appear. As the gangrene develops (fig 2) the pain disappears from the dead area, follows the dying tissue, and continues at its greatest severity until the line of demarcation is definitely established. It is needless to say that a lifeless toe does not cause pain. After the line of demarcation has been reached (fig 3 A), the process of self amputation of the dead tissue sets in and represents the subsiding phase of gangrene. This is well illustrated in figure 3 A, in which the formation of new epithelium is shown along the line of demarcation. The acute and excruciating pain is now replaced by milder burning pain localized to the margins of the sloughing tissues. After the gangrene has completely separated, leaving raw granulations (fig 1 A), there will still be some burning pain on the surface of the healing ulcer until epithelization is well under way. If the patient has been successfully treated over the acute demarcation phase of the gangrene there need be no hesitation in proceeding with conservative measures until epithelization has occurred. Figure 4 represents the healing stages of a gangrenous ulcer. Figure 5 shows a completely healed gangrenous toe after spontaneous amputation of the distal third.

Fig 2—Gangrene. A, acute stage before line of demarcation has been established. B, a few weeks later showing disintegration of gangrenous toes, subsiding phase of gangrene.

of the reserve collateral circulation by the vasoconstricting action of nicotine. One then sees the early signs and symptoms of impending gangrene.

The earliest symptom is the gradual onset of severe pain in the big toe of the affected foot, usually under the lateral margin of the nail. This pain closely resembles that of an ingrown toenail and as a result the patient soon insists on having the nail trimmed or removed in the belief that this procedure will relieve the pain. In a large number of cases this operation has been the starting point of gangrene. Here it is well to emphasize the importance of careful examination of the arterial circulation of the foot before any operation for an ingrown toenail is performed even in an apparently normal individual. At times, even without tampering with the toenail, a small subungual ulcer begins to form, accompanied by increasingly severe pain. The patient now finds it impossible to sleep because of the intense suffering. It is at this stage of the disease that, unfortunately many unnecessary amputations are performed because of the uncontrollable intensity of the pain or because of a mistaken fear that the gangrenous process will spread indefinitely and result in the absorption of harmful toxins. It is just at this point, in my opinion, that the surgeon must exhibit the greatest conservatism and have the courage to tide the patient over until the gangrene has become demarcated. The greatest problem at this time is the relief of pain and it is here that the physician's ingenuity is severely taxed. Furthermore, one will have to contend with this pain throughout the duration of what I call the acute stage of gangrene. It will be necessary here to describe this process in further detail.

After study of a large number of cases of gangrene, one soon becomes cognizant of the fact that the patho-

TREATMENT OF GANGRENE IN ITS VARIOUS PHASES

At the earliest intimation of the onset of gangrene in a toe, it is necessary to carry out the following procedures. In the first place, smoking must be prohibited in absolute terms. This factor is so important that one may expect marked relief from the pain after the patient has stopped smoking for a few days. Furthermore, because of its vasoconstricting action, nicotine will destroy whatever collateral reserve there may be left in the affected extremity and thus cause an unneces-

Fig 3—Extensive gangrene of foot. A, line of demarcation established. B, six weeks later showing shrinkage and separation of gangrenous tissue, note simultaneous healing and epithelization of the proximal margins.

sary increase in the area of eventual gangrene. If an ulcer has developed beneath the edge of the nail, cleansing hot baths containing an antiseptic and deodorant, such as chloramine, should be prescribed. The baths are particularly valuable in the case of ulcers that have become secondarily infected. The practice of surgically removing the nail in the attempt to produce better drainage of the infection is unnecessary and productive of more pain and spreading of the infection.

The cleansing baths are carried out three times a day for periods of fifteen minutes. During the bath the patient is instructed to keep the foot in motion so as constantly to loosen whatever slough or detritus may be present. Following the bath it may be necessary to apply an anesthetic ointment to the exposed portions of the ulcer. This must be applied liberally and in such a fashion that no air comes into direct contact with the gangrenous areas. As the gangrene progresses, the same procedure is continued, namely, chloramine baths

tion of the vein at the site of the injection. This reaction resembles that seen in the treatment of varicose veins by the injection of concentrated salt solution. In these cases, which are rather uncommon, I have found it advisable to use a 3 per cent solution instead of a concentration of 5 per cent.

THE HEALING STAGE

After the line of demarcation has been established (fig 3 A) the acuteness of the gangrenous process may be said to have subsided. The acute inflammatory appearance of the surrounding tissues of the foot changes, and the patient's general condition begins to improve. His appetite becomes better, he is able to sleep, and he loses the feeling of hopelessness and depression which is so characteristic of the early stage of gangrene. It is essential throughout this period to continue the cleansing baths of chloramine solution, as outlined previously. Following the bath a liberal application of a simple soothing ointment should be made. The ointment should cover the gangrenous tissues thoroughly so that all air is excluded from the diseased portions of the foot. If this treatment is followed rigidly and patiently, one soon notices gradual disintegration of the dead tissues (fig 2 B) followed by spontaneous

Fig 4—Usual stages in the healing of a gangrenous ulcer. A, extensive formation of new epithelium. B, complete healing of stump after spontaneous amputation of distal third of toe. C, regeneration of epithelium.

amputation of the toes or other involved parts. Careful examination of the area around the line of demarcation will show healthy granulations beginning to form beneath the disappearing slough (fig 3 B), and within a very short time regeneration of epithelium occurs (fig 4 B and C), which soon covers all exposed healthy granulations, wherever they may be. It is indeed surprising to observe in these cases how dead tissue separates itself with this conservative method. Tendons and bones are sponta-

neously removed without the use of surgical instruments (fig 1 A). I have often compared the spontaneous amputation of these parts to the falling of overripe fruit from a tree. As in the early stages, so in the healing stages it is of the utmost importance that the patient remain in bed. The enormous value of complete rest in bed throughout the entire course of gangrene will readily be appreciated when one observes how well healing takes place even in the presence of diminished blood supply. If difficulty is experienced in the healing of gangrene and gangrenous ulcers, a careful review of the various factors in the treatment must be made to ascertain wherein the fault lies. If, for instance, the patient is surreptitiously smoking, healing will be delayed. If the patient is not kept continuously in bed, healing will not occur. Hospitalization is ideal, but often because of the expense

Complete rest in bed from the onset of the gangrene until the final healing stages is essential. Attempts to heal these ulcers by ambulatory treatment are usually unsuccessful. It is necessary for healing that the affected extremity be kept horizontal at all times. The practice of allowing the patient to sit up with his foot hanging over the side of the bed in the belief that gravity will improve the arterial flow is erroneous. This dependent position soon produces an intense edema of the foot that is not conducive to resolution or healing. If one will observe such an edematous foot after twenty-four hours' rest in the horizontal position, one will see marked wrinkling of the skin of the foot wherever there has been edema. With this method of treatment of the acute stages I have rarely found it necessary to administer opiates. The duration of the acute stage may be from three to six weeks and it is during this period that the greatest number of amputations have been unnecessarily performed by surgeons of limited experience with this disease.

A very important adjunct in the treatment of gangrene in all stages is the internal administration of large quantities of fluids. This may be given in various ways. Some prefer the injection of large amounts of fluids through a duodenal tube. Others prefer the subcutaneous route. I believe the intravenous method to be the simplest and most efficient. The type of solution to be injected is a matter of individual preference. Some prefer Ringer's solution, others prefer sodium citrate or sodium chloride. I am in agreement with Silbert² that hypertonic sodium chloride solution is the simplest to prepare and to administer. The usual procedure is to inject 300 cc of 5 per cent solution of sodium chloride intravenously every other day. It will be found in rare instances that there is a tendency with the use of so concentrated a solution to produce oblitera-

Fig 5—Complete healing.

tion of the vein at the site of the injection. This reaction resembles that seen in the treatment of varicose veins by the injection of concentrated salt solution. In these cases, which are rather uncommon, I have found it advisable to use a 3 per cent solution instead of a concentration of 5 per cent.

After the line of demarcation has been established (fig 3 A) the acuteness of the gangrenous process may be said to have subsided. The acute inflammatory appearance of the surrounding tissues of the foot changes, and the patient's general condition begins to improve. His appetite becomes better, he is able to sleep, and he loses the feeling of hopelessness and depression which is so characteristic of the early stage of gangrene. It is essential throughout this period to continue the cleansing baths of chloramine solution, as outlined previously. Following the bath a liberal application of a simple soothing ointment should be made. The ointment should cover the gangrenous tissues thoroughly so that all air is excluded from the diseased portions of the foot. If this treatment is followed rigidly and patiently, one soon notices gradual disintegration of the dead tissues (fig 2 B) followed by spontaneous

amputation of the toes or other involved parts. Careful examination of the area around the line of demarcation will show healthy granulations beginning to form beneath the disappearing slough (fig 3 B), and within a very short time regeneration of epithelium occurs (fig 4 B and C), which soon covers all exposed healthy granulations, wherever they may be. It is indeed surprising to observe in these cases how dead tissue separates itself with this conservative method. Tendons and bones are sponta-

involved one is forced to treat the patient at his home insisting that he remain in bed at all times. Regularity of the cleansing baths is extremely important. In making up the solution for the bath one must be sure that boiled water is used. The proper selection of ointments is of importance. In the acute stages an anesthetic ointment is to be applied liberally while in the healing stages the use of a nonirritating bland ointment is advocated. In the latter stage it may be possible if the patient is able to endure moderate pain to apply only wet dressings of either chloramine solution or boric acid solution. In any event the routine of treatment should be continued without change until complete healing has been achieved (fig 5).

OTHER METHODS OF TREATMENT

As the clinical course of gangrene and gangrenous ulcers is characterized by rapid development and comparatively slow healing it seems unreasonable to expect to produce healing by agents whose action is spasmodic and temporary. I refer particularly to the use of various vasodilators such as typhoid vaccine and operative procedures on the sympathetic system. The use of typhoid vaccine in any stage of gangrene is attended with the risk of sudden occlusion of large arteries during the period of hyperpyrexia not to mention the discomfort of the high fever and severe chills often associated with nausea and vomiting. Furthermore, there appears to be slight benefit from a transitory vasodilatation in a process that will require weeks or months to improve. The same may be said of the various operations devised to produce vasodilatation by the interruption of the sympathetic pathway in the affected limb. It appears to me that the complexity and risk of the operation of severing the lumbar sympathetic fibers is far too great in proportion to the temporary benefits obtained in these cases which are characteristically chronic in nature.

As far as the Leriche operation is concerned the following quotation from Leriche's own article¹ is self explanatory.

In Buerger's disease periarterial sympathectomy has frequently been tried in the United States. This is wrong in my opinion. The operation can accomplish nothing in thrombo-angitis obliterans for in order to produce its effect it requires at least a partially intact peripheral circulatory system. At the meeting of the American Surgical Association in 1921 I warned certain members against the temptation of trying sympathectomy in these cases. Since that time I have repeatedly published the view that sympathectomy should not be performed in thrombo-angitis obliterans. Nearly all those who have attempted it have failed. Only recently Allen has published eight failures, and in the Royal Society of Medicine of London, Gish, Schesinger and others have reported failures. In these cases I have had no result from extensive periarterial resections and have done no better by dividing the lumbar communicating branches. Briefly I am more and more led to think that no sympathetic operation is of value in Buerger's disease.

INDICATIONS FOR AMPUTATION

Amputation of a leg should be performed only when the gangrene involves the entire foot including the heel. In other words, if it appears that the patient will be left with a foot that will have no functional value it is just as well to amputate below or above the knee. Such extensive gangrene is, fortunately, very rare. Operative amputation of toes or fingers is, in my opinion, usually unsatisfactory and attended with the danger of postoperative spread of the gangrenous area, not to

mention the frequent occurrence of subsequent chronic osteomyelitis.

Pain per se should never be used as an indication for amputation. With the use of properly selected anesthetic ointments, cleansing baths, the prohibition of nicotine and rest in bed the pain can nearly always be controlled. If necessary, opiates may be used until the acute stage is over.

SUMMARY

Gangrene, which often occurs during the course of thrombo-angitis obliterans, is a self-limiting process. Extreme conservatism, even in the severest forms of gangrene, is usually rewarded with an intact extremity, the value of which no one will question. Amputation of a leg should be advised only when it appears that the gangrene will destroy so much tissue that a non-functioning foot will be the ultimate outcome. Pain is no indication for amputation.

Rest in bed, cessation of smoking, cleansing baths, the application of anesthetic ointments and the intravenous administration of large amounts of fluids are the essentials in the conservative treatment of gangrene due to thrombo-angitis obliterans.

RENAL CARBUNCLE*

THOMAS D. MOORE, MD

MEMPHIS, TENN.

Carbuncle of the kidney may be defined as a metastatic circumscribed, conglomerate suppurative process, usually caused by *Staphylococcus aureus*, having its origin in some superficial focus, such as a furuncle, pyonichia or carbuncle. Israel¹ first described the disease in 1901, referring to it as carbuncle because of its striking similarity to an ordinary superficial carbuncle. That the name has met with general acceptance is evident from its employment in the medical literature of the world. It is adequately descriptive of the condition although its pathogenesis differs widely from the ordinary skin carbuncle.

A review of the literature reveals only forty-two cases and reference to twenty-two others, the details of which are lacking. The few cases reported not only may denote the rarity of the disease but also may be construed as indicating the difficulty of diagnosis. It is especially interesting to note that perinephric abscess was present in fifteen of the forty-two cases. There is good reason to suspect that this complication has frequently masked the presence of a carbuncle, as it is a common practice to establish simple drainage in such cases and leave the kidney unexplored. It has been observed previously that superficial septic foci, such as boils and carbuncles, often antedate the onset of a perinephric abscess. Richardson² studied 109 collected cases of perinephric abscess, presumably of extrarenal origin and noted that furuncles preceded the abscess in fifty-five cases and carbuncles in ten. Israel,¹ Barth³ and Eisendrath⁴ after simple drainage of a

perinephric abscess, suspected a cortical renal infection because of continued symptoms of sepsis, and subsequent exploration of the kidney revealed a carbuncle. The wisdom of opening up a wide area in the exploration of a suspected kidney in the presence of a perinephric abscess is open to question. While such a procedure undoubtedly would reveal interesting information concerning the condition of the renal cortex, it would expose the patient to an increased hazard. Lazarus, however, in a recent report, goes so far as to advocate this practice in order that a carbuncle may not be overlooked and no harm apparently resulted in his two cases.

REPORT OF CASES

CASE 1—A boy, aged 11, complained of fever and weakness. Six months before he developed a moderate degree of pain in the right side of the chest, which was thought to be caused by pleurisy. This had been noticed intermittently since. Three weeks before he had been confined to bed for ten days with fever as high as 103 F. At the time of the examination he was very weak and could not walk without assistance. His weight was 65 pounds (29.5 Kg), and, except for slight tenderness over the region of the right kidney associated with some increased muscular rigidity, physical examination was essentially negative. Hemoglobin was 58 per cent and there was a leukocytosis of 11,000. Roentgenograms of the urinary tract and of the chest were negative. The Pirquet test was negative. Tubercle bacilli could not be demonstrated in the urine sediment but culture of the urine in brain broth disclosed hemolytic streptococci.

Fig. 1—Large soft tissue shadow in the region of the lower pole of the right kidney associated with displacement and narrowing of the upper ureter.

On cystoscopic examination the bladder appeared normal and the specimens from each kidney were free from pus and were sterile. Bilateral pyelograms revealed a normal outline on the left but on the right side there was a large soft tissue shadow in the region of the lower pole which displaced and narrowed the upper 5 cm. of the ureter (fig. 1). Exploration of the right kidney revealed moderate edema throughout the

perirenal tissue. There was a large circumscribed suppurating process in the lower pole which was incised and about 2 or 3 ounces of thick odorless pus was evacuated. Free drainage was established and the patient made a good recovery, being discharged from the hospital twenty days following the operation.

This case is of interest in that there was no definite history of a superficial lesion and that the symptoms extended over a period of six months before the diagnosis was established. It is exceptional in that the causative organism was the hemolytic streptococcus. At no time did the urine contain more than an occasional pus cell.

CASE 2—A man, aged 37, gave as his chief complaint rigors and fever. Eight weeks before he had experienced some discomfort in the right side of the abdomen associated with considerable gas but no vomiting or diarrhea. He was kept in bed with an ice bag over the abdomen

Fig. 2 (case 2)—Right pyelogram showing the marked deformity of the pelvis and distortion of the calices is not unlike that caused by a renal neoplasm.

and allowed nothing by mouth for several days. On examination of the urine his physician found pus and during the following three or four weeks he had repeated rigors, high fever and profuse sweats. There had been slight dysuria but no hematuria nor renal colic. The right renal pelvis was enlarged, following which he gradually improved temporarily. During the period of his illness he had lost 25 pounds (11.3 Kg) and physically was very weak.

On physical examination except for evidences of loss of weight the observations were essentially negative. The blood urea and phenolsulphonphthalein output were normal. The leukocyte count was 9,300. The roentgenogram of the urinary tract was negative. The urine contained about 75 pus cells per high power field. On cystoscopic examination the urine from the right kidney was found to contain 3 pus cells per field and from the left it was negative. Indigo carmine returned in good concentration in three minutes from the right and in four minutes from the left. A right pyelogram disclosed a marked deformity of the pelvis characterized by a filling defect and elongation and distortion of the calices suggestive of a right renal neoplasm (fig. 2). Three days later a left pyelogram was made in order to exclude polycystic kidney and was found normal. A diagnosis was made of right renal neoplasm of indeterminate character and exploration of the kidney advised. At operation an extensive localized suppurative process about 7 cm. in diameter was found with destruction of about 50 per cent of the kidney substance. A nephrectomy was done followed by an uneventful convalescence except for a thrombophlebitis.

This case is of especial interest in that the inflammatory process gave rise to a leukocytosis of only 9,300 and the pyelogram was so strongly suggestive of a renal neoplasm that an erroneous diagnosis was made.

CASE 3—A man, aged 51, complained of general weakness, loss of appetite and moderate fever at intervals which had lasted for three months. Several weeks before the onset of these symptoms he had developed an itching between the toes of the right foot which he had scratched. Infection followed and the part became badly swollen with pus formation which confined him to bed for five days and prevented work for a period of five weeks. He was exceptionally healthy

an abscess on his nose and a superficial skin infection of the left wrist. He had lost 22 pounds (10 Kg.)

Physical examination disclosed nothing of importance except for a slight bulging in the right renal area which was not tender. Urinalysis was negative except for an occasional erythrocyte and 6 pus cells per high power field. Roentgenograms of the urinary tract and of the chest were reported negative. The leukocyte count was 22,700 and the hemoglobin was 35 per cent. The patient was hospitalized for further observation. An irregular temperature course continued and

Fig. 3 (case 3).—Only slight deviation from the normal although the kidney was involved extensively.

three days after admission the leukocyte count was 31,900. There was an increased rigidity of the muscles anteriorly and posteriorly in the region of the right kidney. There was essentially no change in the condition of the urine. On cystoscopic examination the bladder was found to be normal and there was an occasional pus cell in the urine from each kidney. A right pyelogram was somewhat indefinite in outline because of underfilling (fig. 3). Not until four days later were there any localizing symptoms, then definite tenderness was elicited and the right kidney became palpable. A second roentgenographic examination disclosed shadows suggestive of medium in the region of the cortex of the kidney at the lower pole. The cystoscopic diagnosis was indeterminate.

Exploration of the right kidney was made the following day and the organ found to be about twice normal size with a large multilocular abscess in the lower pole and several smaller ones in the upper pole. There was about 50 per cent destruction of the renal substance. The patient experienced a very stormy convalescence, developing pneumonia with consolidation of the right upper lobe. Blood cultures on five separate days disclosed staphylococci twice and were reported negative three times. On the ninth day after operation bile was found on the wound dressings and the following day a jejunostomy was performed for postoperative duodenal fistula. The septic condition steadily progressed and the patient died on the fourteenth day following the nephrectomy.

The absence of pain and of urinary symptoms and the practically negative cystoscopic observations in the presence of so many pathologic changes involving the right kidney is of special interest and exemplifies the difficulties of diagnosis in instances of renal carbuncle. These features delayed for a considerable time surgical intervention and were probable important factors in the ultimate mortality.

CASE 4^a—A woman aged 33, gradually developed pain and tenderness in the right loin, associated with fever and urinary frequency. About six weeks before there had been a large boil on the neck, which subsided without incidence. Three weeks before she had been through a normal parturition. Catheterization was necessary the first forty-eight hours. She was discharged from the hospital at the end of the second week and had been up and about the house when the present symptoms began. There was moderate tenderness in the right renal area both posteriorly and anteriorly. The urine contained much pus and an occasional erythrocyte. The blood urea was normal and a roentgen examination of the urinary tract was negative. Cystoscopic examination disclosed a bladder

descensus of moderate degree and 150 cc of residual urine with considerable sedimented pus in the base of the bladder. There was 30 cc of retained urine in the right renal pelvis, which showed 5 pus cells per high power field. There was no retention on the left and the sediment was negative. Phenyl sulphathiazole appeared in four minutes from each side with an excretion of 10 per cent from the right side and 14 per cent from the left in fifteen minutes. Cultures disclosed *Staphylococcus aureus* and *B. coli* on the right; the left was sterile.

Diagnosis was made of small right hydronephrosis with infection, moderate cystocele with residual urine and an acute diffuse cystitis. For a period of three months there were frequent attacks of pain in the loin, rigors and high fever, which promptly subsided on the insertion of an indwelling ureteral catheter which would be left in place for from thirty-six to seventy-two hours. During these attacks the leukocyte count varied from 14,200 to 16,525. A right pyelogram disclosed merely a moderate degree of pyelectasis with no apparent distortion of the calices. As the condition was suggestive of cortical renal infection, mercurochrome 220 soluble was given intravenously on two occasions with no appreciable benefit. During the third month of the illness a blood transfusion was given because of moderate secondary anemia. Three months after the onset following a severe rigor and fever, an exploration of the kidney was decided on. The organ was slightly smaller than normal and there was moderate edema of the perirenal tissues. In the midportion of the convex border was a hemorrhagic softened area about 3 cm in diameter, which protruded slightly from the surface of the kidney. A nephrectomy was done, followed by an uneventful convalescence.

On section in the midportion of the kidney was an abscess surrounded by innumerable smaller abscesses in a localized area (fig. 4). The remainder of the medullary portion was practically normal in color and consistency. The pathologic diagnosis was carbuncle.

The unusual feature of this case was the intermittent attacks of pain in the loin, with rigors and fever which responded regularly to continuous ureteral catheter drainage. Presumably the small hydronephrosis was infected from time to time by the cortical suppurative process and the clinical symptoms can be attributed largely to the small infected hydronephrosis.

CASE 5—A woman aged 40 complained of persistent fever five weeks before an abscess had appeared on the left elbow which was incised and drained. A few days later there was an abscess over the left mastoid region which was treated similarly. Soon afterward fever appeared, which had been constant for more than a month, at times reaching as high as 106 F. Recently dull pain appeared in the right loin associated with moderate frequency of urination.

Physical examination disclosed scars of the recent abscesses. The right kidney was slightly enlarged, easily palpable and apparently enlarged at the lower pole, with considerable local tenderness. Urinalysis was negative except for numerous pus cells. The leukocyte count was 16,500. A pure culture of *Staphylococcus aureus* was obtained from the blood. The blood urea was 45 mg. The roentgen examination of the

Fig. 4 (case 4).—Sketch of sectioned kidney removed at operation. Note the distance of carbuncle from the renal pelvis and the tendency to perforate the capsule.

^a Detailed reports of cases 4 and 5 were given in the Southern Medical Journal (22: 338-345 [April] 1929).

urinary tract was negative. Cystoscopic examination disclosed a moderate degree of cystitis. The urine disclosed no pus but a culture of *Staphylococcus aureus* was obtained from the right kidney and there was no growth from the left. Indigo carmine was slightly delayed in appearance from the right kidney and with slightly diminished concentration as compared with the left. A right pyelogram revealed a definite narrowing and elongation of the lower calyx and was otherwise normal (fig 5 A).

A diagnosis was made of *Staphylococcus aureus* septicemia with a localized metastatic cortical infection of the right kidney, probably a carbuncle. Exploration of the kidney was considered but because of the infection in the blood stream it was decided first to give mercurochrome intravenously. Twenty cubic centimeters of a one per cent solution was given, following which there was a moderate reaction with rapid recession in temperature, which after a few days remained normal. The patient soon felt much better generally and at the end of a week was able to be up and about. The enlargement and tenderness at the lower pole of the right kidney gradually disappeared and on repeating the right pyelogram seventeen days later, there was the interesting revelation of a reversion to normal of the lower calyx (fig 5 B). No infection was present and the differential functional test (phenolsulphonphthalein) was normal, 17 per cent from the right and 12 per cent from the left in fifteen minutes. One year later she considered herself entirely well.

For obvious reasons, pathologic proof of the existence of a carbuncle is lacking in this case. The clinical diagnosis, however, seems justified in view of the recent abscesses of the skin followed by pain in the renal area, the recovery of *Staphylococcus aureus* from the urine of the infected kidney, the function of which was diminished, and a palpable enlargement and tenderness of the lower pole of the kidney, with a corresponding deformity in the pyelogram, which disappeared after intravenous chemotherapy.

ETIOLOGY

Men are more commonly affected with renal carbuncle than women. Of forty-seven cases including the five here described, fifteen occurred in women and thirty-two in men. Three instances of the disease in children, all aged 10 years, are recorded by Barth,³ Beer⁷ and Colmers.⁸ Zinn⁹ and Reschke¹⁰ each had patients aged 55, which is the most advanced age recorded. Twenty-eight patients were in the third and fourth decades. Trauma in the region of the kidney may be a factor, illustrated by the cases of Thompson,¹¹ Smirnov¹² and Kohler.¹³ Brewer¹⁴ demonstrated experimentally that trauma to the kidney prior to inoculation of bacteria usually leads to localization in that organ. The greater exposure of men to trauma may explain the higher incidence of the disease in that sex.

The primary focus is usually a superficial lesion caused by *Staphylococcus aureus*. It may have been an insignificant boil, self-treated and all but forgotten by

the patient before the onset of renal symptoms. Of forty-seven cases, furuncles are mentioned in twelve as the probable source. Carbuncles in various locations occurred in eight cases and paronychia in six. Among unusual foci may be mentioned an abscessed tooth, which was removed,¹⁵ and phlegmon of the hand.¹⁶ Smirnov¹² regards acute respiratory infection as the probable source in three of his cases. In ten cases the nature of the original focus remained obscure.

PATHOLOGY

The lesion begins in the cortex as an interstitial infection. The abscess is usually composed of a number of suppurative foci in a localized area. The lesion may become surrounded with a zone of fibroblastic tissue and give the appearance of encapsulation. It is usually limited to the cortex and tends to spread toward the capsule rather than invade the renal pelvis. Capsular perforation leads to perinephric abscess, which in some cases gives rise to the first local symptoms. The uninvolved portion of the kidney remains normal to a surprising degree. This feature, together with the

Fig 5 (case 5)—A slightly elongated and narrowed lower calyx. B pyelogram made seventeen days following intravenous chemotherapy. Note change in lower calyx.

limitation of the process to the renal cortex, explains the negative urinalysis so common in these cases. A multilocular abscess may occur and in some instances more than one carbuncle may exist in the same organ.¹ It is rarely bilateral, only three cases having been reported.¹⁵ Microscopically the purulent foci have the usual characteristics of suppurative lesions: necrotic debris and closely packed infiltrating leukocytes. *Staphylococcus aureus* is usually found in pure culture. A marked fibroblastic reaction surrounds the zone in which the blood vessels are dilated. The adjacent renal tissue shows very little change.

Considered pathologically renal carbuncle is evidently not a clear-cut, distinct entity. Neff¹⁷ believes that the renal carbuncle of many writers is the infarct, septic infarct, multiple abscess, conglomerate abscess, or

solitary abscess of others. Dick¹ refers to the condition as staphylococcal suppurative nephritis. There seems to be no good reason, however, for confusing it with septic infarct although it is probable that a fully developed carbuncle has had its origin in a septic embolus. It is important that it should not be confused with focal suppurative nephritis, as described by Brewer.

DIAGNOSIS

The clinical and laboratory data pointing to the renal condition may be very meager. This is well illustrated by one of the cases of Neff¹⁹ which was studied over a period of thirty-seven days under close observation in a hospital before the diagnosis was established. In a case reported by Becht²⁰ thirty-four days elapsed after admission to the hospital before a renal carbuncle was diagnosed. The chief diagnostic difficulties may be briefly stated as follows: 1. The almost complete absence of localizing symptoms is not unusual unless perinephric abscess complicates. 2. Urinalysis may be practically negative, as in thirty-three of the forty-seven cases. 3. A long period elapses between the original skin focus and symptoms referable to the renal infection. In twenty-five cases this interval averaged thirty-one days. Frequently the history of a superficial septic lesion may not be discovered until after the diagnosis is established. 4. Pyelography displays no characteristic features. In one of the cases here reported the pyelogram strongly suggested a renal neoplasm and led to an erroneous diagnosis. Individual calices may be elongated and the pelvis compressed. A large carbuncle in the lower pole may exert pressure and distort the course of the upper ureter. 5. Differential functional tests are of great value and may constitute the only clue to the presence of the renal lesion.

CLINICAL FEATURES

The onset of the symptoms of malaise, headache, fever and loss of appetite may at first suggest typhoid. Pain in the loins may be present from the first but frequently does not appear until later on in the course of the disease or simultaneously with the onset of a complicating perinephric abscess. It is usually associated with definite tenderness in the costovertebral angle. Repeated rigors are not uncommon and fever may reach a high degree. Leukocytosis of from 10,000 to 20,000 is the rule. Higher counts may indicate perinephric abscess. In cases of long continued fever with no local renal symptoms, the impaired function of one kidney, as revealed by a differential functional test, may furnish the only valuable clue.

TREATMENT

Of the forty-seven cases, primary nephrectomy was performed in twenty-one, with two deaths, incision and secondary nephrectomy in seven, with no deaths, incision and drainage only in thirteen, with two deaths, incision and secondary excision of the carbuncle in two with no deaths, enucleation of the carbuncle¹⁹ in two cases, with secondary nephrectomy in one, with one death.

In uncomplicated cases primary nephrectomy, therefore, seems the most certain and safest means of dealing with the disease. In late cases complicated by perinephric abscess, drainage followed by a secondary nephrectomy is desirable. Whenever possible the carbuncle itself as well as the perinephric abscess should be drained. In thirteen cases so treated, the incision and drainage sufficed, secondary nephrectomy not being

necessary. Neff¹⁹ has noted that a line of cleavage may be found about the carbuncle permitting enucleation of the septic mass. Following any measure less radical than nephrectomy, a persistence of high fever and other toxic symptoms usually indicates the necessity for removal of the kidney.⁴ From a study of sixteen cases, Colmers⁶ advocates nephrectomy as the treatment of choice of these patients, four died following nephrotomy, two died without the benefit of surgery and ten recovered following nephrectomy. In one of the cases here reported in which all the classic symptoms and evidences of carbuncle were present, the patient promptly recovered following intravenous chemotherapy. I have been unable to find the record of any other case that did not require surgical treatment.

SUMMARY

Carbuncle of the kidney is an unusual clinical entity, evidently often overlooked because of its frequent association with perinephric abscess, and further because of the difficulties in many instances of a definite diagnosis. The detailed observations from a study of forty-two collected cases are presented and five additional ones are reported. The chief clinical feature of the disease are as follows: There is (a) a recent history of a suppurative lesion such as a furuncle or a carbuncle. (b) From three to five weeks later, dull pain appears in the region of the affected kidney, associated with local tenderness, fever and sweats. Rigors may or may not occur. (c) The laboratory data usually includes practically a negative urinalysis, moderate leukocytosis and a positive culture of *Staphylococcus aureus* from the affected kidney, the function of which may be moderately diminished. (d) Pyelography reveals no characteristic changes and may simulate a picture of a renal neoplasm. (e) Surgical intervention is usually imperative, nephrectomy being the treatment of choice. In cases complicated by perinephric abscess preliminary drainage is desirable prior to nephrectomy.

20 South Dunlap Street

ABSTRACT OF DISCUSSION

DR D. K. ROSE, St. Louis: The points that I get out of this paper are that this is a definite pathologic entity, that surgically, it is blood borne, and that the diagnosis is admittedly difficult. In analyzing these cases, there is the explanation of many difficult diagnoses: that is, septic temperature for some time with indefinite physical signs and negative urinary conditions with the diagnosis suddenly becoming more clearly one of perinephric abscess. This is suggestive that the perinephric abscess is secondary to the carbuncle, and, when there is such a sequence of events, wouldn't it be advisable to explore the kidney rather than simply to drain the abscess? In the cases in which the diagnosis of perinephric abscess is easily made in its early stage wouldn't it be less advisable to explore the kidney but rather only to drain the abscess? Some of these specimens also suggest that secondary foci in the kidney occur after the formation of perinephric abscesses. Undoubtedly, however, the majority of the lesions are secondary within the capsule of the kidney.

DR HAROLD I. MORRIS, Detroit: I agree with everything Dr. Moore has said. In Detroit the dictum has been laid down by an authority in the urologic world that there is no such thing as a unilateral renal carbuncle. The point of view taken was that, in consideration of a unilateral involvement, the staphylococcus being blood borne, did not occur and that renal cortical infection was of necessity bilateral. The very fact that time is a factor in the diagnosis of renal carbuncle, I think will satisfactorily explain the delay in diagnosis when there is present perivertebral tenderness rather sudden onset with or without symptoms such as frequency and hematuria following the upper respiratory tract infection of an acute type or following the

removal of tooth or tonsil or the acute exacerbation of foci elsewhere. I think that this type of renal infection is entirely different from the renal carbuncle which has been described, and which I think is the correct interpretation that should be put on this particular condition. In my experience, a nephrectomy is seldom necessary. If time is taken, as it should be, before this diagnosis is established, these infections are walled off and, I believe, in the majority of cases, as Dr Moore's statistics show, free incision and adequate drainage is sufficient. Of course, if the kidney cortex is destroyed, nephrectomy is necessary.

DR CHARLES P. MATHÉ, San Francisco. I am glad to hear Dr Moore describe carbuncle of the kidney as a definite clinical entity. In 1925, I reviewed the literature and added the report of a case occurring in a young school teacher in which the carbuncle was secondary to two boils of the neck and in which staphylococci were found in the boils in the blood stream and in the carbuncle itself. One should not confuse the urogenic type of kidney abscess, which is usually associated with stasis and chronic pyelonephritis, with renal carbuncle. The latter is a staphylococcal infection in the cortex of the kidney secondary to lesions in the skin, such as boils, furuncles, paronychia and carbuncles. The organisms are transmitted by the blood stream and lodge in the end arteries of the kidney or perirenal fat. When they lodge in the glomeruli they lead to the formation of solitary or multiple abscesses, suppurative nephritis or to carbuncle, which is characterized by a large central area of necrosis surrounded by numerous smaller abscesses. When they lodge in the perirenal fat they give rise to a perinephric abscess. The latter may be secondary to suppurative processes in the kidney, but a kidney abscess is rarely secondary to a perinephric abscess. The diagnosis is sometimes extremely difficult. Renal carbuncle is likely to be confused with influenza, gallbladder disease, appendicitis or other abdominal lesions. It is differentiated from pyelonephritis by the paucity of urine observations as compared to the illness of the patient. Staphylococci are usually present and can be found if the urine is centrifugated for a sufficiently long time. Some important points in diagnosis have not been mentioned. These consist of immobility of the affected side. The diaphragm fails to move with respiration and there is lack of mobility of the kidney, which is easily demonstrated in making a pyelogram in the vertical position. In doubtful cases, an early exploratory incision should be made. Early intervention gives one an opportunity to perform the conservative operation of drainage or excision with cautery. It also lessens the likelihood of invasion of the opposite kidney.

DR THOMAS D. MOORE, Memphis, Tenn. The point that Dr Mathé raised regarding immobility of the kidney is in line with some cases reported in the literature. Some writers have described an almost cartilaginous capsule. This was not encountered in the cases reported.

Investigations with Calorimeter—The Atwater Respiratory calorimeter, the first apparatus of the kind to be used in America, was not only large enough to measure with a high degree of perfection the amount of heat given off by a man at rest or at work, but it was also possible to measure the oxygen consumed, being in many respects the most important form of respiration calorimeter yet devised. The accuracy of the apparatus was remarkable, as was shown by burning a given weight of ethyl alcohol in the chamber the carbon dioxide recovered being 99.8 per cent of the theoretical value and the heat production 99.9 per cent. With this apparatus was inaugurated a series of investigations of the greatest physiological value in the study of human nutrition. A credit to American enterprise and scientific acumen.

Thus they showed that the heat produced by a man in a given period of time is the same in quantity as that which can be derived from the energy liberated in the oxidation of food materials during the same period, that the energy which a man expends at hard work is the exact equivalent of the energy liberated by the body metabolism. Especially noteworthy is the fact that these investigations demonstrated for the first time on man the application of the principle of the conservation of energy to the human organism.—Chittenden R. H. The Development of Physiological Chemistry in the United States. New York: Chemical Catalog Company, 1930.

ROENTGENOGRAPHIC STUDIES IN NORMAL OSSEOUS DEVELOPMENT*

E. KOST SHELTON, M.D.
SANTA BARBARA, CALIF.

This study in osseous development, based on the original observations of Engelbach and McMahon,¹ was undertaken (1) to present a more practical and modern set of tables and roentgenograms of the normal osseous development for every year of age from birth to 20 years, (2) to present the opinions of other observers and attempt an explanation of their variations, and (3) to demonstrate further the practicability of such a standard in the differential diagnosis of the endocrinopathies.

Since the studies of Engelbach and McMahon were published, other and varied opinions of independent observers have appeared. While all have been of measurable value in a further elucidation of the subject, a certain amount of confusion persists. It is believed that much of this is based on a diversity of opinion as to what constitutes a normal subject. If it is true that osseous development becomes, at times, an index to biochemical health, the rapid advances in this important phase of medicine makes it increasingly necessary to redefine the term. Heretofore, an individual free from the gross evidence of infectious and parasitic disease, metabolic disturbance, new growth and deformity was considered normal. So-called constitutional inadequacies, unless grossly represented in the somatic make-up or accompanied by signs and symptoms long associated with the older conception of disease, were rarely taken into consideration. The roentgenogram was seldom employed in such a diagnostic capacity.

That retardation of osseous development is pathognomonic of early hypothyroidism is well established. Comparatively few hypothyroid children, however, present the classic evidence of cretinism or myxedema, unless the condition is far advanced. As a consequence, many are considered normal until some outspoken evidence of the deficiency is presented in later life. It is equally certain that the onset of adolescence (gonadal function) has something to do with the epiphyseal closures. In America, this occurs in the female more commonly between the ages of 12 and 14 and yet a girl who began menstruating at 10 and one who has not menstruated at 16 are frequently considered normal, provided they fall within the previously accepted standards. Considering the possibility that many individuals of a like nature have been used in the statistical data gathered by others, it is remarkable that no greater variations have occurred. In my choice of a normal subject, I have attempted to exclude all the endogenous factors which may influence the osseous development from birth to 20 years. After the first year, a variation of six months above or below the accepted standard for the age is considered within the normal.

There is another factor of equal importance, the element of time. Heretofore it has been impossible to determine the exact meaning of such terms as first and second years. For example, many interpret the first year as being anywhere from birth to the first

anniversary of the birth day, which is undoubtedly correct. Others look on such a period as lasting until the child is 2 years of age. The latter argue that an infant is 1 year old until its second birthday. In order to obviate this confusion it has become necessary to prepare a series of roentgenograms based on a specific time, namely, the birthday. Since the actual time of

from birth to, and including, the fifth birthday. Osseous centers that are new to the age are indicated by an asterisk, those that were present the previous year, and are merely repeated, do not have the asterisk. Thus the full development is presented each year. Although a study of the six major joints has been made, only those which show some definite change from the

appearance and union of an ossification center will ever be variable within a certain number of months, the occurrence is considered relatively unimportant. The practical application resolves itself into a series of comparative roentgenograms for a given age.

INFANTILE PERIOD

Table 1 shows the joint to be roentgenographed and the osseous centers which we consider normally present

previous year are considered. The wrist, for example, is used at 1 year (12 months) but not again at 2 (24 months), since there is no additional osseous development aside from the general growth of that already present. At 3 (36 months), however, the wrist is again considered to show the presence of the triangularis and the epiphyses of the metacarpals and phalanges which have appeared sometime during the course of the previous year.

It can readily be seen that the observers Baetjer and Waters,² Knox,³ Rotch,⁴ Poland,⁵ Cohn,⁶ and Allen⁷ are in remarkable accord, as to the time of appearance, during this period of life. All of them, with the exception of Poland, whose observations were made many years ago, agree that the distal epiphysis of the femur and the proximal epiphysis of the tibia, together with the talus, cuboid and calcaneus, should be ossified at birth. It is therefore evident that the absence of these nuclei in the knee and ankle would point to a retardation of osseous development during the intra-uterine period, prematurity, of course, excepted

cretins in whom slight modification of stature is noted, but markedly retarded differentiation of somatic tissue occurs. It appears reasonable, then, to assume that an absence of one or more of these nuclei at birth is an early and recognizable sign of hypothyroidism. The same relative need for a standard of comparison holds true throughout the infantile and juvenile years in which means of estimating the basal metabolic rate are as yet inadequate. Figure 3 shows the wrists of three hypothyroid children compared to the normal for the age. Not one of these patients presented the classic textbook picture of cretinism.

Fig. 1—Normal osseous development infantile from birth to 2 year

Figures 1 and 2 show the roentgenograms that pertain to this age.

From a study of the phylogenesis of the endocrine system, borne out by the work of B. M. Allen and others in the removal of the thyroid anlagen in tadpoles, one is led to believe that the thyroid produces a hormone of tissue differentiation rather than one of growth. There is clinical evidence of this in many

True mongolism, birth injuries and other forms of mental deficiency do not consistently retard the unfolding of the osseous system, although hypothyroidism is occasionally associated with such conditions and must consequently give a confused picture. Rickets may be easily excluded by clinical and roentgenologic observations peculiar to the disease. Of equal importance are the endocrinopathies that tend to further the somatic growth. Hypergenitalism (precocious development and function of the genital system), the etiology of which is more or less obscure, is always accompanied by a rapid unfolding of the osseous system with an early closure of the epiphyses. Figure 4 shows the hand of a child with microgenitosomia and one with hypothyroidism compared to a normal for the age. Not

only is the roentgenologist able to predict something of the subsequent development in such an individual but a closer study would, in all probability reveal points in the diagnosis of hitherto unsuspected value

JUVENILE PERIOD

Table 2 (from 6 to 12 years) shows the additional osseous centers and the beginning of the unions particularly between the ischium and the pubis and between the trochlea and the capitellum. It will be seen that the greater the age, the greater the variation of the authorities. As pointed out by Pryor,⁸ Bundy Allen⁹ and others, sex begins to play an important part in the latter

menstruation or, in the male, by hyperplasia of the genital apparatus. There are borderline cases, however particularly in the younger ages, which only a comparative roentgenogram will reveal.

The role assumed by the anterior lobe of the hypophysis in growth and development, with its two distinct hormones, the one effecting general somatic growth the other, genital development and function, affords excellent opportunities for roentgenologic research. Early gigantism, characterized by unusual deposition of calcium salts together with rapid growth of the long bones, and its antithesis, hypophyseal infantilism, are more easily recognized by a comparative study. Hypo-

Fig. 2.—Normal osseous development infantile from 3 to 5 years

years of this epoch, the female tending to be slightly in advance of the male. It is my belief, however, that no great difference occurs in the normal before the thirteenth birthday and that for practical purposes one table for both sexes, considering the variation allowed, is adequate. Figure 5 shows the roentgenogram pertaining to the age. The practicability of such a normal standard is again urged in the diagnosis of premature, retarded or arrested development. Precocity may be otherwise obvious, as shown by the early onset of

thyroidism, with or without the association of other endocrinopathies, may, if congenital, or if acquired and of long standing, be demonstrated quite as effectively in this period. Figure 6 presents the hands of three hypothyroid children in the juvenile age compared to the normal. A marked retardation of osseous development is noted in the classic cretin, aged 8.

ADOLESCENT PERIOD

It has long been known that gonadal function plays an important part in the closing of the epiphyses. It is equally well established that the onset of adolescence is variable within a certain number of years. From a recent study of the students in a private school for

day with an average of 15 years. While this is slightly in advance of the general average for the United States it must be remembered that in previous statistics little

In these years also a remarkable difference is first noted between the sexes. While it is much harder to determine the exact time of onset of male adolescence,

it must be conceded that it occurs on the average of from one to two years later than in the female. In a like study on the students of a private school for boys it was found that approximately 70 per cent of

those considered developed secondary sex characters and had the first spontaneous ejaculation between the ages of 14 and 16 with an average of 15 years. Ninety per cent of the remainder came within six months of
